LIST OF ILLUSTRATIONS IN VOLUME XL.

	PAGE		PAGE
Four Illustrations of Gunshot Wounds of the Larynx.....	30	Six Diagrams representing Cardinal Aspects and Sections of a Limbless Vertebrate.....	113
The Architecture of the Spinal Cord.—Section of the Cord below the Medulla Oblongata.....	33	Diagrams illustrating the Relations of the Meson to the Picture-plane	114
Section of the Cervical Enlargement of the Cord.....	33	Two Ways of placing Antimesal Figures for Comparison. Three Diagrams.....	115
Section from the Dorsal Regions of the Cord.....	33	Two Instructive Modes of placing Figures of Transections for Comparison. Two Diagrams.....	115
Section of the Lumbar Enlargement of the Cord.....	33	Hypertrophy of the Mucous Glands of the Lips. Three Illustrations.....	152, 153
Diagram illustrating the Relations of the Nerve-fiber Tracts in the Spinal Cord.....	34	The Surgeon's Pocket-Case. Twenty-one Illustrations.....	153-156
A Diagram designed to show the Areas of the Crossed and Direct and Crossed Pyramidal Tracts in a Section of the Spinal Cord and the Fibers that compose Each.....	35	Cohen and Richardson's Compressed Air Apparatus.....	424
A Diagram illustrating the Development of the Different Systems of Fibers in the Spinal Cord.....	36	Brain Disease (probably Syphilitic).....	431
Diagram of a Transverse Section of Spinal Cord in Upper Half of Dorsal Region.....	36	Dupuytren's Contractions of the Fingers. Two Illustrations.....	467
Diagram of a Spinal Segment, designed to show its Component Parts.....	37	Dart, removed from the Bronchus.....	487
A Diagram designed to illustrate the Circle of Reflex Action in a Spinal Segment.....	37	A New Varicocele Clamp.....	591
A Diagram designed to illustrate the Paths of Motor and Sensory Conduction in the Spinal Cord.....	37	Result of Operation for the Relief of Bow-Legs.....	639
A Handy Pocket Ear-Case. Eighteen Illustrations.....	54, 55, 56	Artotype Reproductions of Photographs of the Larynx and Posterior Nares.—Normal Larynges in Pronation.—Normal Larynges in Respiration.—Chronic Catarrhal Laryngitis.—Paralysis of the Arytenoideus Muscle.—Swollen Arytenoids in Laryngeal Phthisis.—Growths in the Larynx.—Posterior Nares in Hypertrophic Nasal Catarrh. (Facing).....	653
A Diagram designed to illustrate the Connections of the Motor and Sensory Conducting Tracts with the Spinal Nerves.....	65	Apparatus for photographing the Larynx.....	654
A Diagram designed to represent the Various Paths of Sensory Conduction in the Cord.....	65	Method of photographing the Larynx.....	655
Paralysis of the Left Vocal Band. Three Illustrations.....	91	A New Apparatus for Transfusion.....	657
		Three Illustrations of Adenoma of the Petrous Portion of the Temporal Bone.....	662, 663, 664

Original Communications.

THE SIGNIFICANCE OF GLYCOSURIA
IN CONNECTION WITH
DISEASE OF THE BRAIN AND CERVICAL CORD,
AND WITH DEMENTIA PARALYTICA.*BY ALLAN McLANE HAMILTON, M. D.,
NEW YORK.

THE occasional association of sugar as a urinary constituent with cerebral disease has attracted the attention of many recent observers, the latest of whom is De Jhonge,† who has brought forward a number of cases of disease of the pons and bulb, and has traced the relation between pathological changes in these regions and glycosuria and polyuria. Some of De Jhonge's cases show that disease and injury of the upper cord, with or without ascending degeneration, often give rise to very decided diabetic symptoms. Hayem found in two cases of glycosuria that gelatinous deposits and hyperplasia of connective tissue were present at the floor of the fourth ventricle, while Liouville and Potain found that the urinary deposit was associated with tumors which pressed upon the floor of the fourth ventricle and adjacent parts. Glycosuria has also been detected in connection with anterior cerebral disease, without bulbar lesion, by Chassaignac, who related the case of a man who fell from the sixth story of a building, sustaining a fracture of the right frontal bone and a lesion of the anterior lobe, and died three days afterward; but this case I think is exceptional.

In some of De Jhonge's cases there were œdema and albuminuria, while in others glycosuria was the only symptom. Friedreich, Stanley, Hayem, and Piorry have also brought forward examples which show that disease and injury of the upper cord, with or without ascending degeneration, often give rise to very decided diabetic symptoms.

It is unnecessary to refer to certain general forms of functional and organic disease of the brain in which polyuria may be a symptom. In most of these it is very probable that the posterior basal portion of the brain is involved, and in many cases the polyuria is of a character that can not be mistaken. The limpidity of the urine is a distinguishing feature, its specific gravity may be as low as 1.000, and as much as ten litres daily may be passed without any great loss of weight or strength. Such a condition of affairs I have repeatedly found to exist among hysterical women, and there is a variety of frontal headache I often find, the subjects being usually men who pass immense quantities of limpid urine during or after the paroxysm.

It is not of these cases I particularly wish to speak tonight, but of those of unmistakable organic disease of the brain in which glycosuria accompanies bulbar symptoms. Sometimes there may be albumin in association with sugar, and nearly always the quantity of urine has been greatly

augmented. Several years ago I found that in the early stages of general paresis of the insane there was very often glycosuria in connection with the pupillary and speech defects, a conclusion which has borne out the researches of Magnan, who considers the primary lesion to be medullary. Merson, who goes extensively into the urinalogy of general paresis, does not mention the appearance of sugar (in fact, I find no record of any search for it), but, while he holds that in the average number of cases there is no increase in the amount of urine excreted by these patients, he admits that in some cases there is a notable increase.

I recently saw a case which presented the features of a hybrid general paresis with bulbar, and finally very marked and persistent renal symptoms, the amount of urine voided daily exceeding twenty ounces at times, while at others it was scanty, but contained albumin or sugar at all times. During the past six weeks the patient's legs and feet have been the seat of a puffy swelling, the skin being red and glossy; and there was very slight pitting on pressure, which disappeared in the course of a few days. The patient's disease began with embarrassment in articulation, pupillary alteration, tremor of the tongue, and finally of the whole body, and then came the delusions of grandeur, which were of the most extravagant nature, and he became salacious in the extreme. Nearly all of the cranial nerves were affected. There were facial anæsthesia, impairment of smell and taste, and very curious vaso-motor changes, which consisted mainly in a discoloration of the skin of the left arm and hand. From time to time I found sugar in his urine, and this seemed to be the case after an attack of excitement.

With the kind assistance of Dr. Landon, of the Hudson River State Hospital for the Insane, I am enabled to present the records of urinary analyses in twelve cases of general paresis of the insane, which were made every day for fifteen days. In these patients the bulbar symptoms were marked and the urine was increased in quantity. In all there was a varying amount of sugar.

It may be stated that these patients were upon the same diet and treated precisely alike, so the results have more value than if the cases were selected at random.

Of these twelve cases, it will be seen that in two there was "considerable" sugar, and in one case there had been some months previously a large quantity found. In Case 6 both albumin and sugar were found. On ten occasions the former was present, and on five absent. It is to be noted that, as a rule, when albumin was present the sugar was not to be found, and *vice versa*. The quantity of sugar seemed to bear no important relation to the quantity of urine, and on days when no sugar was found the patient often passed from 50 to 60 oz. In some of the cases, however, this was not so.

In Case 1 the patient passed from 48 to 64 oz., and upon every occasion but one sugar was found, while in Case 2 rarely was more than 44 oz. passed, and this was on a day when the tests were negative. In one case (No. 8) the urine was of low specific gravity, pale in color, and greatly increased in quantity. None of the patients whose urine was examined got alcohol in any form during the time the ex-

aminations were made. During the time the tests were made there were no influences, so far as was known, that

* Albumin upon ten occasions. † Five months ago considerable.

could have affected the excretion of sugar. The physical symptoms were those ordinarily observed in cases of general paresis—motorial disturbances, such as tremulousness of the tongue and of the muscles of the upper and lower extremities, difficulty in swallowing and articulation, and fibrillary twitchings. R. W. C. and W. H. R. are bed-ridden. In the other cases the gait is more or less uncertain and staggering. H. C., J. P., R. W. C., M. M., W. H. R., and E. C. have partial or complete paralysis of the sphincters. All the patients are in a demented condition to a greater or less degree. J. H. P., R. W. C., J. P., M. M., and W. S. have exalted delusions.

The tests used for the determination of sugar were Fehling's (the solutions being freshly prepared), chromate of potassium, and the carmine-indigo.

Merson's observations are valuable in showing the fact that the quantity of uric acid is increased in the majority of

cases, while phosphoric acid and the chlorides are diminished. The amount of urine, estimated according to the weight of the body in seventeen cases examined by him, was slightly in excess of that excreted by six healthy men. Taking the standard of Parkes, which is fifty-two ounces, the quantity of urine in my cases was diminished; but, according to the estimates of Dalton, which seem more reasonable, and taking into account the amount lost during defecation, which it was impossible to collect, I am quite sure that there was, especially in Cases 1, 8, and 10, a notable increase. If we take special days, as in Cases 1, 8, and 10, there can be no doubt of this. The average specific gravity in Merson's cases was 1.019, in my own 1.0228. The maximum specific gravity in Merson's seventeen patients was 1.032, in my own 1.035.

Ebstein is the only observer, so far as I know, who has found glycosuria as a symptom of epilepsy. A remarkable case of this disease came under my observation a few weeks ago, in which saccharine urine was a feature. The attacks were of a type which is somewhat unusual, and certain symptoms suggested an invasion of the cerebellum and possibly the bulb. Mr. T. is a stock broker, aged thirty-eight. He had, eight years ago, while upon the floor of the Exchange, a convulsive attack, attended by loss of consciousness, and his body was drawn to the right side. He had three more of these the same day, and each day since has had from four to six, the immediate cause being excitement. The seizures were rather of the nature of *petit mal*, but he has had two attacks of *grand mal* at night, when the convulsions were very severe, both forearms and hands being flexed and the head drawn backward. There was stupor, which deepened, with stertorous breathing, and recovery followed in five or ten minutes. During my visit he had two light attacks, the first of which occurred when he took my hand for the purpose of shaking it. He then suddenly lost consciousness and began to moan, the sounds being rhythmical. The body was drawn over to the right side in tonic spasm, the head bent toward the right, the eyes were open, and the pupils widely dilated. He was exceedingly livid, and the pulse weak and intermittent. The loss of consciousness was transitory, and he made a quick recovery. On a subsequent examination his tongue pointed to the right side, the face was drawn to the left, and the tendon-reflexes were increased on the left side. He has had attacks of transient ataxic aphasia, diplopia, and formication of both lower extremities, but no anesthesia, and has had seizures when he would walk in a circle. There was advanced neuritis in both eyes. The second attack, which occurred during my visit, was somewhat curious, and came on while I was testing his patellar reflex, when his body was drawn to the left side instead of the right, and the right tendon-reflex became exaggerated. There is sometimes an epigastric aura. No ascertainable cause exists, and the patient absolutely denies syphilis. In this case much interest arises from the fact that during the past six months the patient has passed great quantities of urine, and examinations, made both by his own physician and by myself, show large amounts of sugar. In this case also there was unequal vaso-motor disturbance in the lower extremities.

THE TREATMENT OF EPILEPSY.

By LANDON CARTER GRAY, M.D.,

PROFESSOR OF NERVOUS AND MENTAL DISEASE, NEW YORK POLYCLINIC; PHYSICIAN-IN-CHIEF TO THE DEPARTMENT OF NERVOUS AND MENTAL DISEASE ST. MARY'S HOSPITAL, BROOKLYN.

(Concluded from page 714, Vol. XXXIX.)

Eclampsia, it is well known, is but a term that is sanctioned by usage to designate a convulsion occurring in children or from some unmistakable cause—as pregnancy, uræmia, organic cerebral disease, etc.—ceasing upon removal of the cause, and seldom leading to general and gradual deterioration of the mental faculties. Eclampsia is, in other words, an acute convulsion, relatively innocuous. Epilepsy, on the other hand, is a term denominating a series of convulsions usually occurring at intervals throughout some period of time, and entailing serious alteration of the mind and nervous system; or, in brief, epilepsy is a chronic convulsive disorder. The one is, by itself, so far as the single fit is concerned, clinically indistinguishable from the other. Eclampsia may, therefore, very properly be said to be an acute epilepsy, and epilepsy to be a chronic eclampsia. How, then, are we to tell, when confronted with a convulsion in a child, either below three years of age or above, whether we are in the presence of epilepsy or not? We may weigh probabilities—that is, we may guess, and guess *ad libitum et in infinitum*, but we can not be certain. The convulsion may never be repeated, or repeated a few times only during the years of childhood, or it may recur at varying intervals throughout the passing years, until the dread conviction steals over us that the *morbus sacer*, the fell disease of the inscrutable gods, is indeed before us. It would be most consistent with facts to regard every convulsion in childhood with solicitude. The following cases will, I think, substantiate these statements:

Male, aged twenty. Grand mal once or twice yearly since she was a year and a half old.

Male, aged five. Grand mal since one year of age.

Male, aged ten. Grand mal since one year old.

Female, aged eight. Had convulsions when about three years old. None again for six years. The next interval was about eleven months, and the last interval, before coming to me, about three weeks.

Female, aged thirteen. Had a fit when about eighteen months old, while cutting her teeth; another, when four years old, during scarlatina. None again till the eleventh year, since when patient has had grand mal.

Female, aged three. Has grand mal, which began when she was six months old.

Female, aged twenty-three. When about eighteen months old had a fit, ascribed to eating pickles. Another in seventh year, attributed to the same cause. About thirteen months after this fits began to come steadily, and she has now grand mal.

Gowers,* speaking of the same aspect of the question, says: "A large number of cases, no less than twelve and a half per cent. of the whole, commenced during the first three years of life. In this group no cases of simple infantile convulsions are included, only such as, beginning in infancy, continued as chronic epilepsy. There is a difficulty in ascertaining the exact date of commencement in all cases.

* *Op. cit.*, p. 14.

Of about one third, all that could be learned was that they began in infancy. . . . The number of cases is largest in the first year (five and a half per cent. of the whole), and falls rapidly to three years of age, and then more slowly until five, when the minimum for the early period of life occurs—only one seventh per cent. commencing."

Dr. Gowers obtained these figures from an analysis of 1,450 cases.

Occasionally it will happen that a seeming malarial attack will, in a person predisposed to epilepsy, be the immediate cause of the attacks, which will cease upon treatment of the seeming malaria.

R. D., aged fourteen. Lives in a malarious district. About six years ago had two or three fits. None since, until a late attack of malaria, which appears every week in the afternoon—which day can not be ascertained, nor as to whether there is regular periodicity—being characterized by the typical cold, hot, and sweating stages, during which the fits have again occurred; never at any other time. There is an abdominal aura with cry, unconsciousness, foam at the mouth, clonic convulsions, but no sleep afterward; only a yawning and wearied feeling. Tongue clean; bowels regular. The child was placed on a milk and farinaceous diet, was given a cholagogue, alkalies, later on a bitter tonic, and had no return of the fever or fits for five months that it remained under my treatment. I know nothing of its subsequent history.

The question of epilepsy from so-called reflex irritants is one of some clinical importance. As we have seen, epilepsy is readily influenced by many reflex impressions; so that we can comprehend that—as I know to be a fact from oft-repeated experiences—a circumcision, a removal of preputial adhesions, a divulsion or cutting of urethral strictures, a clitoridectomy, an operation upon the vagina or uterus, a nerve-stretching, a trephining, may each have a temporarily beneficial effect upon an epilepsy. But do genital or other reflex irritations ever cause an epilepsy? This is a matter as yet *sub judice*. I have never seen epilepsy caused by genital irritations, or heard of it, although I have both seen and heard of cases alleged to have had such a causation, in none of which, however, had the foregoing considerations been sufficiently weighed to render the proof adequate. It would certainly seem that distinct irritation, as by tumor, of peripheral nerves could set up epilepsy, and especially has this been so in those cases of laryngeal epilepsy or vertigo induced by tumors of the vocal cords.* Other than this, the subject needs elaboration.

We should, therefore, keep this picture of an epilepsy clearly before us: Easily influenced by manifold impressions, whether of medicaments or upon nerves of general or special sensation; occasionally quasi-periodical; occasionally inter-convertible with migraine; often occurring at long intervals, generally at very irregular intervals; occasionally manifesting itself, to all appearance, in a solitary convulsion; occasionally beginning in early childhood or infancy; at times seemingly stimulated to activity by malaria; possibly caused by special reflex irritations.

I presume it will be understood that I am referring

throughout this paper to that form of epilepsy which is functional in the sense that it is not caused by underlying recognizable organic disease of the brain or cord. Epileptic convulsions—or, as they should be styled, *epileptiform* convulsions—that proceed from intra-cranial syphilis, myelitis, disseminated sclerosis, meningitis, tumors of the cerebro-spinal axis, vertebral disease, etc., constitute an entirely different group of symptoms, as need hardly be said.

I know of no writer who has taken full account of all these characteristics of epilepsy. Yet there can be no question whatsoever but that no just conclusions can be based upon the results following any method of treatment unless all these characteristics are kept in mind. An interval of ten or twenty years may be ascribed to some pet method of treatment, doubtless often has been, by one ignorant of the fact that cases may run in this way when left untreated; or an epilepsy, inter-convertible with a migraine, may temporarily seem to improve to one who is not alive to the fact that the migraine is growing worse, and may do the patient as much harm as the unchecked epilepsy; or enthusiasts may laud to the heavens some new operation—such as the latest surgical novelty of tying the vertebral artery—some varying time after which the epilepsy is better; or other enthusiasts may, in like manner and with like reason, claim cures for new medicaments.

The treatment of epilepsy should, therefore, embrace many other details than the mere administration of drugs. Anything that might possibly act as a cause or an excitant must first be sedulously sought for, and, if it is possible to do so, it should be promptly removed. Even though we can not bring ourselves to believe that it is adequate to set the epilepsy agoing, we should have no right to indulge our doubts at the possible expense of our patient. In the terse phrase of the lawyers, we should give our patient the benefit of the doubt. The simple question should be: Is the removal of the possible cause or irritant likely to do more harm than its presence? If not, it should be removed. For this reason I always remove all genital irritations, either of the male or female, as well as all peripheral irritations of any kind. In cases of injury to the skull, when there is reason to suspect a fracture of the inner table, or some intra-cranial disease beneath the point of injury, I believe that the trephine should be used unhesitatingly. The operation is attended with little danger, by it some serious irritant may be removed, and, even in the event that no focus of mischief is discovered, temporary improvement will be almost certain to follow. In other words, the operation may do great permanent good, is almost certain to do considerable temporary good, and is almost certain to do no harm.*

The natural course of the particular epilepsy which we are treating should also be studied. We should gain as accurate an idea as possible of the frequency of the fits; whether they are of the nature of *grand mal* or *petit mal*; what relation in frequency the attacks of *grand mal* bear to those of *petit mal*; whether there intervene mere muscular twitches or mere vertigo, and how often; what the intervals are between the different individual fits and the differ-

* "Laryngeal Epilepsy," L. C. Gray, "New England Med. Monthly," Nov., 1882.

* I hope, at some future time, to dwell at length and in detail upon the considerations that should prompt the use of the trephine.

ent groups of fits; how these intervals vary from time to time in their average, and their minimum and their maximum. In endeavoring to ascertain this, it will not do to trust entirely to the patient's memory, for not only is that defective, but the patient can not, of course, know anything of what transpired during his unconsciousness except what is afterward told to him. I make a rule, therefore, of obtaining this history from some near relative.

In the treatment of the epilepsy itself, the bromides certainly seem to be the remedies that are most effective. If statistical proof be asked in support of this opinion, it would be impossible to give it, because almost all the statements of writers are full of the errors that I have alluded to. Indeed, I can not conceive how it would be possible to prove the superiority of one anti-epileptic treatment over another unless it should happen, as it has never done, that some one treatment promptly cured the disease outright. In order to carry out such a comparison of treatments, we should need at least fifty to one hundred patients for each particular method; and if we were only to test the drugs that have their advocates at the present day—the bromides, belladonna, oxide of zinc, nitro-glycerin, borax, digitalis, ligature of the vertebral artery—we should require three hundred and fifty to seven hundred patients. The imagination stands appalled at the myriads of victims who would be needed to set at rest the conflicting claims of all the remedies that have been popular at different times. It would not do to go into our public institutions for these, inasmuch as such patients consist of the most inveterate, generally hopeless, cases. We must depend, then, for our human supply upon out-door clinics and our private practices. But, even supposing that this number of patients could be seen in private practice and out-door clinics, it would be simply impossible to keep them under observation long enough to be certain of results. The basis for the statement of this superiority of the bromides is in the widespread professional belief to this effect. Many other remedies have worked seemingly brilliant results. The great Trousseau narrates some excellent cases in which belladonna has been very effective. Schroeder van der Kolk gives some remarkable accounts of how he successfully managed apparently hopeless cases by means of issues and setons. Kuntze speaks of great improvement from the administration of woorara. But of no one drug is the testimony to its efficacy so great as it is with the bromides. From all countries, in many languages, by specialists and non-specialists, the praises of the bromides are sung. Yet, while I believe that this wide-spread belief is fair evidence that the bromides are superior to other remedies, I can not admit the cures that are claimed for them, because, as I have endeavored to demonstrate in this paper, cases are seldom kept under observation long enough to make sure of a cure, and also because we can only determine approximately, in any given individual, what shall be called a cure.

The abundant physiological researches that have been made into the action of the bromides, more especially of the bromide of potassium, have made clear that their chief effect is as a depressant of certain involuntary reflexes. Thus, a frog poisoned by this method could not be made to exhibit

ordinary reflex actions at the same time that all voluntary movements were properly performed. H. C. Wood, whose *résumé* of the subject is painstaking and judicious, believes that this depression of reflex action is due mainly to the effect of the drug upon the spinal cord. Large doses depress the heart—whether from direct action upon the organ itself, or from an abolition of the reflex of the cardiac centers, is as yet undecided.* Clinical evidence, supplementing the physiological, has shown that the bromides will abolish the pharyngeal reflex without any simultaneous impairment of sensation, will greatly impair the memory, may even cause a spurious aphasia, will weaken the intellect, depress the spirits, impair digestion, depress the vaso-motor system, produce great muscular weakness, and, in some exceptional instances, superinduce maniacal excitement.† The bromides would therefore seem to be depressants of certain portions of the central nervous system, such as are necessary for the performance of certain reflex actions. Ordinarily this sedative action is one that is remarkably safe as regards life. I have repeatedly given children as much as 3 ij to 3 ss. of potassium or sodium bromide daily steadily for months with good results, and I am constantly giving these doses to adults for long periods of time. In testing a plan of treatment recommended by Dr. Gowers, I have several times given an ounce of the potassium bromide at one dose, with no other result than to lower the pulse some twelve to eighteen beats for a few hours.

But there are certain individuals, constituting a very troublesome minority, who are dangerously susceptible to the action of the bromides. An epileptic patient of mine, a boy of ten, although robust in appearance, was yet reduced to a condition of imbecility and such general weakness that he could not rise from bed by a three days' treatment with ten-grain doses of the bromide of potassium. He passed out of my care into the hands of a gentleman who ordered him to take the bromide for three months. He took to bed as before, and, when he came out of it, he went to Greenwood Cemetery. An epileptic, demented youth was brought to my clinic. I ordered him a mixture containing potassium bromide, gr. xv, and sodium bromide, gr. x. I was sent for in hot haste shortly after he had taken his first dose, found him in a state bordering on collapse, and had great difficulty in restoring him. I saw in consultation, some three years ago, a young lady who had had a few epileptic attacks, for which she had been steadily treated with large doses of the bromides during a period of about six months. She was in bed, almost pulseless, pallid, thin, exhibiting great mental sluggishness, being made to answer questions with great difficulty, weeping at times without cause, somnolent. Her life had been despaired of, and two eminent gentlemen had made a diagnosis of grave organic nervous disease. I recommended the withdrawal of the bromides, the substitution of stimulants, tonics, and a nourishing diet, and the patient was about in a few weeks. A professional gentleman who consulted me had had some commingled malarial and lithæmic symptoms which had been diagnosed as cerebral congestion, and the bromide of potassium

* H. C. Wood.

† Bannister.

was ordered. It was taken for about four months, in twenty-grain doses thrice daily. The result was to impair a naturally fine and unusually vigorous mind to such a degree that the memory was seriously affected, an emotional state was induced to such an extent that weeping would follow the most trivial incident, and most of the day was spent in sleep. I have never seen a more pitiable spectacle than this naturally energetic, robust, and keen-minded individual after four months of this accursed treatment. A few weeks of tonics, stimulants, and good diet restored his tone to a large degree, but it was fully two years before he recovered his former energy of mind and body. I am constantly seeing such cases as these, and, together with other ill results that have come to my notice from the wholesale use of the drug at the present day, they have made me seriously aware of the fact that the bromides are necessary evils. We should so regard them in the treatment of epilepsy. Not one grain more should be given than is absolutely necessary.

I usually begin the treatment with ten-grain doses of the potassium bromide twice daily, and double the dose at night, as suggested by M. Brown-Séquard, because the interval between the evening and the morning doses is longer than that between any others. The quantity is gradually increased by five grains at a dose every few days until the pharyngeal reflex is abolished or the attacks diminish. This abolition of the pharyngeal reflex, which was first suggested as a criterion by Voisin, can be tested by means of a spoon or a spatula touching the pharynx. In the majority of cases, when this is abolished it is safe to stop increasing the dose, because, for a time at least, the epilepsy will be held in check. But it is by no means the infallible test that it is stated to be. It will often be abolished without the epilepsy being affected to any great extent; or, in other instances, the epilepsy will improve long before it is abolished. If, then, this reflex of the pharynx disappears, I pause in the dosage, and wait to see whether the symptoms improve. Should the symptoms improve before this reflex disappears, I also pause in the dosage. I then begin to habituate my patient to the dosage to which I have attained, which, by the by, varies very greatly with different individuals. Usually by this time the patient shows distinct signs of bromism, pallor, quicker and weaker pulse, dull visage, perhaps a foul breath, sometimes drowsiness in the daytime. The next problem to which I set myself is to drive off these so-called signs of bromism without at the same time diminishing the influence of the bromides over the epilepsy. This seems paradoxical at first sight, but I know that it can be done, as I pointed out several years ago,* and I do it by the addition of alteratives and tonics—if need be, even of stimulants—to the bromides. If the individual is in very poor general health, I use tonic doses of quinine for a few days; and I do this in some cases from the start. But the larger number of patients do best upon cod-liver oil and arsenic, or iron, if there is any anæmia. I always look carefully after the diet, seeing to it that they obtain as much nutritious food as their age, habits, race,

heredity, circumstances, and health will enable them to properly digest and assimilate. I am forced to put the matter in this general way, because, were I to go into all the dietetic details, I should write another paper as long as this.

This process of getting the patient habituated to the bromides is one that requires a variable time in different persons. As a rule, it is done in about a month, but some organisms will tolerate the drug well almost from the start, while with others it needs months, and upon some it will have such pernicious effects that it must be discontinued at once.

Having habituated the patient in this manner, I let him go steadily along without any alteration in his medicines until the improvement shows some signs of arrest. Then, if the patient has so far borne the bromides well, I increase each dose by five to ten grains. If, after another period of improvement, there again comes a relapse, I push the dose still further, and, if need be, increase it again and again. Sooner or later, however, a point will be reached when it becomes evident that it would be dangerous to increase the dose, and still the disease is evidently not entirely under control. For a long time I was baffled when I reached this point. But I ascertained that if now, without diminishing the dose that we have been giving, we administer some other of the drugs that have been found to be anti-epileptic, we can usually hold the malady still further in check. Of these adjuvants, I prefer, in the order in which they are named, sodium bromide, belladonna, digitalis, borax. With the ammonium and lithium bromides I have had too limited an experience to enable me to speak positively, although I think they will act about as their sodium fellow does. The oxide of zinc has not been successful in my hands. I like the digitalis in asthenic cases, and the belladonna in children. Ringing the changes upon one or the other of these drugs, I keep steadily on with the treatment so long as I maintain a control of the epilepsy. By this time it is generally the case that the better part of a year has passed by, or even a year or two. When it becomes plain that the epilepsy is slipping from control, I proceed to make some radical change in the treatment. Should the patients' circumstances permit it, I have them obtain an entire change of air. To others I give a vigorous emetic, or a sharp purgation, and follow it up with a decided change in the diet; and then I begin another long course of treatment with another of the drugs which I have named, making the others act as adjuvants from time to time, but in a different order from that in which they were given before.

With this method of treatment, I find that I am able to keep under control most of the cases of epilepsy that are brought to me. I do not pretend to have made absolute cures. Some of my patients have gone long times without fits: one over three years, and several for two to three years.

The quasi periodicity to which I have alluded has often a practical importance. Where these quasi-periodical attacks are far apart, as every month or at longer intervals, it may be possible to control them by administering the bromides at about the time when they are to be expected, and not in the interval, the patient being thus spared all the enervating effects of the drug. With individuals who live mainly

* "The Use of Quinine with Nervous Sedatives," "Arch. of Med.," Oct., 1880.

by their mental efforts this may be an extremely important desideratum, for I am fully persuaded that no man's mind is up to par when that man is under a course of the bromides. But it is not every case that can be safely treated in this way, for while in some the epilepsy will be held perfectly in abeyance, in others, when thus checked at its regular periods, it will break out, often with increased violence, at unusual times, then necessitating the continued treatment. Every quasi-periodical case should, for this reason, be carefully studied.

An epilepsy that is inter-convertible with a migraine must also be treated through the latter disease. In addition, then, to the anti-epileptic medication should be employed such remedies as extract of *cannabis indica*, caffeine, the alkalies, etc.

In conclusion, I desire to emphasize the fact that the general health of every epileptic must be sedulously cared for by every resource of medical art. It is too much the custom to give the bromides and do nothing further.

Those individuals, not infrequently encountered, upon whom the bromides act so deleteriously, will usually respond, to a certain extent, to belladonna and the other remedies. But it has been my experience that such cases are usually very intractable; so that such a peculiar susceptibility to the bromides is of great prognostic value.

A special method has lately been advocated by Dr. Gowers. It can be best described by him:

"Begin with doses of two to three drachms of bromide every second or third morning, and increase the dose to four drachms every fourth morning, and six drachms or an ounce every fifth morning. . . . The object is to give the nervous system, as it were, a series of blows with bromide in order to facilitate the occurrence of the condition which bromide produces in patients who are cured of epilepsy by its use. . . . The maximum dose should be reached in two to three weeks, repeated three or four times, and the doses then gradually reduced, so that the whole course lasts six or seven weeks."*

I am sorry to say that a trial of this method upon six patients failed to give as favorable results as the continuous bromide treatment, although the precautions recommended by Dr. Gowers were carefully observed.

I look to the future for the specific for epilepsy. In the present condition of our knowledge I do not believe that we can do more than check the manifestations and the progress of the disease; and my paper is intended simply as a contribution to the rational medicine of the subject.

THE THERAPEUTIC USE OF THE DIGESTIVE FERMENTS.†

By HERBERT E. SMITH, M.D., NEW HAVEN, CONN.,

LECTURER ON CHEMISTRY IN THE MEDICAL DEPARTMENT OF YALE COLLEGE.

I THINK you will agree with me in the statement that, although the various digestive ferments have been very largely used, it has been with but partial success.

* *Op. cit.*, p. 259.

† An abstract of a paper read before the New Haven Medical Association, June 16, 1884.

In considering the subject, we may very properly ask whether this result is due to inefficiency of the preparations which have been furnished us, or to errors in our methods of administration, or whether we have expected more from their use than is reasonable.

In opening the discussion, I will make no attempt to formulate a reply to these questions, but will call attention to such functions and uses of these ferments as seem to be of therapeutical importance. This can be most readily done by considering them in three divisions of a natural chemical classification:

I. *The Enzymes acting on Starch* are diastase of malt, ptyalin of saliva, and the unnamed diastatic ferment of the pancreatic secretion. The product of the action of these substances was, until recently, considered to be glucose. Musculus and others have shown, however, that very little glucose is formed, but that the starch is for the most part converted into maltose and various dextrins.

It has been assumed, and is so taught in all text-books, that the starches and sugars are absorbed in the form of glucose, and this on no better ground than that the absorbed body reduces cupric hydroxide as does glucose. Some statements on this subject have recently appeared which are of quite a new character. I refer to the publication in the "Chemical News," by Dr. F. W. Pay, of a series of papers on the physiology of the carbohydrates, in which the author shows, by an ingenious method of analysis, that there are agents in the walls of the stomach and intestines which convert glucose and cane-sugar into maltose and dextrins, and, further, that after the ingestion of these sugars no trace of them is to be found in the portal blood, but only maltose and dextrins.

This work has not yet been confirmed, but is interesting as indicating a simpler method of dealing with the carbohydrates than has been supposed to exist.

Of the commercial preparations which we have at our command, certain of the extracts of malt are very active diastatic agents. Much has been promised by the manufacturers of pancreatin, but I think that we shall be disappointed if we rely upon these preparations for this purpose. Thus I found that, judging from the amount of copper hydroxide reduced by the product formed, 1 c. c. of saliva transformed more starch in five minutes than one grain and a half of pancreatin did in two hours. And this was a sample given to me as an active diastatic agent.

To meet, then, an indication for the use of a diastatic ferment, a good extract of malt is at present our only agent.

The liquid, beer-like preparations, of which Hoff's is an example, will not serve for this purpose, as in them the ferment is mostly destroyed in the process of manufacture. The preparations to be used are the concentrated extracts like Trommer's, and maltine, which are solutions of diastase in a thick sirup of maltose, dextrins, and extractives of the grain used. The substances, although in great part fit for immediate absorption, can, of course, amount to but little as food when given in the usual medicinal doses.

From what is known of the conditions in the stomach, I believe that diastase can act with saliva during the first part of gastric digestion. So that it can be administered

immediately after meals, or, better, used not as a medicine, but as an addition to, or seasoning for, the dish of oatmeal, boiled rice and milk, or of gruel. It should be added just before eating, and at a temperature not above what can be borne in the mouth. The taste is quite like that of sorghum syrup, and not disagreeable to most people.

The chief indication which occurs to me for the use of ferments of this class is that of acid eructations following the ingestion of carbohydrates and due to the acetic- and butyric-acid fermentations.

It seems desirable in these cases to hurry the decomposable bodies out of the stomach before these fermentations can be established.

II. *Proteolytic Enzymes*.—There has been, and I think there still is, much confusion in the minds of some physicians and manufacturers regarding the properties and uses of pepsin of the gastric juice and trypsin of the pancreatic secretion.

Following Defresne and earlier experimenters, some of the text-books now in use are not correct on these points, according to the more recent results of Kühne, Chittenden, Langley, Roberts, and others, who have investigated the relations of the ferments to one another, and to acids and alkalies.

The following statements may be easily confirmed: Pepsin is completely destroyed by the action of a free alkali, or alkaline salts, such as sodium carbonate. Trypsin can act in the presence of very dilute acids, but is quickly destroyed by hydrochloric acid of the strength of the gastric juice, this destruction being accelerated if pepsin is also present. These statements concerning trypsin are also true of the animal diastatic ferments. With these facts as a basis, it would seem an easy matter to indicate the best method of administering these substances for medicinal purposes. Such, however, is not the case. It is only recently that we have found a reagent for distinguishing between a free acid and an acid in loose combination with proteids. And we do not know how the formation of these combined acids may have affected our experimental results. Von d. Velden says (*"Zeitsch. f. physiol. Chem.,"* iii, p. 205) that the first appearance of free acid during gastric digestion varies with the nature of the food ingested between 45 m. and 2 h. Uffelmann gives the limits as 45 m. and 1 h. (Maly's *"Thier-Chemie,"* 1880, p. 302). Ewald (*ibid.*, p. 303) denies that the period is so long. If it is of any such considerable length, it is possible that the ferments, which are destroyed by the gastric juice of full acidity, may act to some advantage during this time, as I have said of the diastatic ferments.

If, therefore, pancreatin is to be given immediately after a meal for its effect on proteids, it must be with the understanding that, at the best, the conditions are not so favorable for its action as for that of pepsin, and that it is very doubtful if any considerable part of a dose can pass through the pylorus before sufficient acid is secreted to destroy it.

Some of the preparations to be found in the market are nearly valueless, as a so-called pure pepsin which I found to be almost without action on fibrin. But this is true of many remedies, and is to be avoided by using the goods

of reliable houses. Certainly many of the scale pepsins and pancreatins are very efficient preparations, and likely to become more so from improved manufacturing processes.

The saccharated preparations may, of course, be good, but can not be recommended, as they are liable to falsification, and are very easily prepared extemporaneously if desired.

As we believe that we consult our best interests by prescribing our own mixtures instead of the nostrums of the manufacturers, so it seems to me we should do by avoiding the many digestive compounds which are poured upon the market. Some of them are incompatible mixtures; as, for instance, the liquid preparations which are similar to lactopeptine in the claim that they contain all of the digestive principles. To be complete, as some one has well said, they only require, in addition to the free acid present, also some free alkali. For without it the trypsin and diastatic ferments would be completely destroyed by the pepsin and acid in the time that must elapse between manufacture and consumption. Others are curious examples of polypharmacy, like the one which contains in the dose recommended, besides other things, one fifteenth of a grain of diastase and one fourth of a grain of maltose.

The starch would suffer very little, I fancy, from this amount of ferment. The object of the one fourth of a grain of maltose is difficult to understand when one reflects that one third or more of all the starch ingested is absorbed as maltose. Other examples could be cited, if necessary, to show that there are in the market preparations which are inefficient from lack of active principle and from bad pharmacy, and that they have been largely used. The digestive ferments have never with certainty been prepared in a pure state. Therefore the commercial articles, however good, contain an uncertain but considerable amount of inert matter. Hence, if one of these impure pepsins is given, as I have seen it, in half-grain doses, it seems as if it were expecting too much to look for any marked result.

These substances are used also, I think, in cases where they are not necessary or where they are not the best means to meet the indication. Thus a quantity of pepsin may be put into the hands of a patient with directions to take it when needed. Left in this way, the need is more frequently felt and the person learns to depend upon this artificial help, when, perhaps, the secretions could have been increased by a continued stimulation, such as can be effected by the use of sodium carbonate, before meals, by bitter tonics, alcoholics, and possibly in the case of the pancreas by ether.

The objects to be aimed at in the use of the digestive ferments, it seems to me, are, first, not to supplant but to assist the natural processes, and thus to maintain the proper bodily nourishment while the secretions are being established, if this result can be obtained, as in the case of many convalescents; and, second, to maintain the nutrition during a temporary disability, as in fevers and gastric ulcer.

To meet the first set of cases, pepsin can be given by the mouth after meals in one dose of from five to ten grains, or, as seems more rational, in divided doses, at intervals during digestion, in the form of soluble pills or tablets.

This is the most natural use that can be made of any of the ferments, and seems to be the best means of attacking the proteids within the body. Pepsin can be given with hydrochloric acid if desired, or in powder with sodium bicarbonate, with the expectation of stimulating the secretion of acid. Though owing to the destructive action of the temporarily strong alkaline solution which must exist in the stomach, it is more rational to precede the meal with the carbonate and follow it with the pepsin.

If it is desired to exhibit trypsin in suspected intestinal indigestion, this may be accomplished at the close of gastric digestion, when it should be given well protected by sodium carbonate. Advantage may also be taken in these cases of partially digested milk, or such milk served up in the form of jellies, blanc mange, etc., which can be easily done. I say partially digested, for one pint of milk treated at the temperature of the body with five grains extract of pancreas will acquire as distinctly a bitter taste in a half-hour as will be relished by most convalescents. To meet the indications in the second class of cases mentioned, the digested milk or milk gruel seems to be especially applicable, though the digestion may be continued longer, as from one hour to one hour and a half, since the taste is not so likely to be objected to by a fever patient.

I have only to call attention to the value in these cases of the artificial digestion by trypsin, for the preparation of enemata.

III. *Action of the Enzymes on Fats.*—Fats are doubtless absorbed chiefly in the form of an emulsion. Hence it seems desirable to possess some agent that will further this process. Preparations of pancreas are said to do this, and are frequently used for this purpose. A fresh pancreas, ground up with oil, certainly forms an emulsion which is permanent for some hours. An oil which contains a little free fatty acid readily forms an emulsion with a solution of sodium carbonate.

If the pancreatic juice contains a ferment, as has been claimed, that splits fats into glycerin and free acid, this would readily explain the formation of an emulsion with the alkaline secretion. But Roberts ("On the Digestive Ferments," etc.) states that he has found no acid in mixtures of extract of pancreas and oil short of the time in which the action of bacteria would effect that result. And, further, that he has been unable to make an extract of pancreas that would form an emulsion with fats.

These statements, together with our common experience, would seem to teach that, whatever the action of the secretion, the extracts of pancreas thus far furnished us are, in spite of their claims, quite devoid of any emulsive action.

SOME COMPLICATIONS OF ORDINARY LABOR.

By W. H. HAYNES, M.D.,
NEW YORK.

THESE CASES are presented as illustrating points in the practice of midwifery overlooked or merely mentioned in works on obstetrics, with directions for treatment tending to their successful terminations.

CASE I.—*Premature Rupture of the Membranes, and Ankylosis of the Sacro-coccygeal Articulation.*—Mrs. H. K., aged twenty-six, a native of Ireland, is a stout woman, of good health and appearance. She has never suffered from any menstrual difficulty. Ceased menstruating for the first time about the beginning of December, and expected to be confined early in the September following. Enjoyed excellent health, and gained flesh during pregnancy.

About noon of the 31st of August I was called to see her on account of her having passed a large quantity of whitish fluid *per vaginam*, about 10 A. M., without any warning or pain before or after its occurrence. At the time of my visit she was discharging small quantities at intervals. I learned that she had undergone considerable excitement and exertion during the previous night, having had to ascend and descend the numerous flights of stairs in a high tenement-house, where she lived on the top floor. Examination *per vaginam* revealed the cervix uteri soft and dilated to the size of a silver half-dollar, and the finger came immediately in contact with the head in the left occipito-iliac anterior position. Fœtal heart heard in the left iliac region. Directed rest in bed and quietness.

I was again called to her at 11 P. M. of the same day. Learned that she had commenced having pains in her back about 6 P. M., and at the time of my arrival she was having good uterine contractions at intervals. Examination revealed the head flexed, descended, and almost wholly rotated. In withdrawing my finger, I recognized a bony prominence just beneath the posterior vaginal wall, a short distance in front of the advancing head. This I found to be the coccyx firmly ankylosed to the sacrum, at an angle which would impede the natural and early expulsion of the child by diminishing the antero-posterior diameter of the inferior strait.

The labor progressed satisfactorily, the head rotating and being forced down to the prominence formed by the coccyx with each wave of contraction, till finally it became firmly impacted in the outlet of the pelvis. When this stage of affairs was reached, and I found no further advance was made, notwithstanding good uterine contractions, with the assistance of my friend Dr. Hathaway the forceps was applied and the head readily extracted. After removing the forceps, a few pains delivered her of a large-sized, live female child. The placenta was readily extracted. The perineum having been lacerated, the wound was cleansed and sutured. She had no trouble of any kind during her lying-in, and the perineal wound was all united when I ceased attending her two weeks later. Her subsequent labors have each time necessitated a similar treatment.

The two points to which I will draw attention in the above-recorded case are premature rupture of the membranes and sacro-coccygeal ankylosis.

Premature rupture of the membranes is usually the result of a combination of two or more of the following conditions: Abnormal thinness of the membranes; or excess in quantity of the liquor amnii, with a sudden and forcible entrance of the head into the excavation of the pelvis; or the occurrence of painless contractions due to exertion or injury of various kinds; and meddlesome or criminal midwifery. It may occur as long as four or five days previous to the commencement of labor, or only after the first few pains, before dilatation of the cervix is complete, and is to be diagnosticated from a somewhat similar condition known as hydrorrhœa. This is accomplished with certainty only by a physical examination, when in a case of ruptured membranes the finger will reveal absence of fluctuation

and ballottement within the uterus and come directly in contact with the head through a slightly dilated cervix; whereas in hydrorrhœa the os will be undilated, the cervix of normal length, and fluctuation and ballottement obtained. Another element in the diagnosis will be the period of gestation at which the woman has arrived. If the discharge takes place close upon her expected accouchement, it will more probably be due to rupture of the membranes, whereas hydrorrhœa occurs most frequently during the period of gestation between the fourth and seventh months. In both conditions the proper course of treatment to pursue is rest of every description.

I have met this condition of premature rupture of the membranes chiefly in primiparæ, and the cases have invariably presented some difficulty, so that I am guarded as to the prognosis, and prepare to meet complications in such instances. A complication which may occur with premature rupture of the membranes, especially in cases of distorted pelvis and abnormal presentations, is prolapse of the funis. This is to be borne in mind, sought for, and proper treatment instituted for its relief.

Another result which may follow, and has been produced by the same accident, is hæmorrhage from within the uterus. This will cause grave anxiety, and calls for active treatment, which is fully given in the various books and is not within the scope of this paper.

Ankylosis of the sacro-coccygeal articulation in women is a condition found to exist in a certain proportion of those who have passed the period of adolescence, usually after twenty-five years of age without child-bearing, and in consequence of natural or diseased processes. It may be partial or complete as regards the number of pieces of bones involved and fibrous or bony in its nature, and is most readily felt with the finger in the rectum. Not in all cases does the angle formed by the coccyx offer any interference with the natural mechanism of labor, but in some few cases the bone is turned so acutely forward and so firmly fastened as to lessen the antero-posterior diameter of the inferior strait and cause consequent impaction of the head in the outlet of the pelvis. This necessitates either a fracture of the (now one) bone, allowing the head to pass, or the assistance rendered by the forceps in compressing and molding the head so that it will pass the obstruction. Of these two modes of treatment, the former is the one advocated by all writers, but one which I have been unable to accomplish, and have therefore resorted to the latter, which I have found, in the three cases of this nature I have met with thus far, to be an easy, safe, and rapid one. The former method may succeed in cases of partial or fibrous ankylosis which present only a slight obstacle, and where nature will generally complete the labor unaided. This deformity in itself never reaches such an extent as to require any other operative interference.

CASE II.—*Shortness and Rupture of the Funis*.—Mrs. A. T., Italian, aged twenty-three, is a robust, healthy woman, pregnant for the first time. Has enjoyed good health during gestation.

About noon she first felt the pains of commencing labor. At 8.30 p. m., when I saw her, she was walking about, suf-

fering from pains in the back and abdomen, recurring every few minutes. On examination, the finger revealed the soft parts dilatable, with the os open to the size of a fifty-cent piece. Membranes not ruptured. Head small, and presenting in the left occipito-anterior position. Pelvis of normal size. At 9 p. m. the membranes ruptured. By 11 p. m. there had been but little advance, with the pains becoming of short duration and slight effect, and recurring at long intervals. Finally, the head entered the excavation of the pelvis. During all this time, and subsequently till delivery was accomplished, she was continually desiring to sit up, and did not aid herself at all with bearing-down efforts, but complained of a severe pain in the lower part of her abdomen, even during the intervals between the contractions. At 1.30 a. m.—the head presenting at the vulva, and the pains still failing to appear in sufficient force, duration, and frequency, and, on their subsiding, the head receding as much as it had advanced, notwithstanding the aid I rendered by external and internal manipulations—I gave a full dose of ergot. This had the desired effect, so that, with the assistance I rendered, she was delivered of a small, live male child at 2 a. m. I had previously ascertained that the cord did not encircle the child's neck, but in the delivery it was so short that it broke midway in its length ere allowing separation of the child from its mother, and bled profusely from the fetal extremity. It was necessary to extract the placenta manually, as it was for a small extent adherent to the anterior wall of the uterus. The exact length of this short cord I unfortunately forgot to note at the time and will not guess at it now. Nothing worthy of note occurred during her lying-in.

The cause of the protraction in this case became perfectly apparent at the completion of the labor, and confirmed a suspicion I had formed as to its nature—viz.: that some condition within the uterus was, so to speak, holding the child back, the cord, of course, being the most natural one, and which I at first expected to find coiled one or more times around some portion of the child, thus artificially but practically shortening it, which is a condition more commonly met with, and giving rise very often to similar symptoms. Thus, while this is the only case of decidedly short funis I have met with, I have had the proportion of one coiled funis to every four cases of midwifery that have fallen to my lot, in half of which number ante-natal symptoms pointed to that fact. These symptoms, which were well portrayed in my case—the constant pain in the uterus which is complained of by the patient, and can be differentiated from the other pains attending the parturient process; constant desire to maintain a sitting posture; absence of all desire to assist nature with bearing-down efforts; advance and recession of the head till it becomes stationary; peculiarity of the contractions, becoming short and inefficient; with no other obstacle to a quick and easy delivery—rendered the diagnosis easy by both direct evidence and exclusion. Other symptoms which may be present are: indentation of the uterine wall at the insertion of the placenta, due to traction; convulsive movements of the child and appearance of blood in the discharges at a late period, from laceration of the cord or separation of the placenta. By physical examination we may feel either a tense uncoiled cord, or a portion of it coiled around some part of the fetus, usually the neck.

The condition shown by this train of symptoms may

result simply in a protracted labor that otherwise would have been rapid; strangulation of the part of the child that the cord encircles; rupture of the cord; or premature separation of the placenta, allowing of a hæmorrhage and inversion of the uterus.

The different plans of treatment advised for this complication are: the efforts of nature, assisted by position, the woman squatting, sitting, or in the genu-pectoral posture; external abdominal compression; looping down the cord over the head; allowing delivery through the coils; assistance rendered through the rectum; ergot, the forceps, and severance of the cord.

In the majority of cases the efforts of nature, assisted by position, manipulation, and sometimes ergot, will accomplish a successful result, as in the above-recorded case; but in two cases of coiled funis I have failed by these methods, and have had to resort to the forceps for accomplishing the delivery, each time with success. The necessity for a cutting operation will be very rarely called for, judging by the scarcity of reported instances, and only in cases of imminent danger after the former methods have failed, as it will be found a difficult operation, liable to be attended with injury to both mother and child.

I have had another case of rupture of the cord near the fetal extremity during a precipitate labor, the child falling to the floor, while the woman was in the erect position, before I was in attendance, but causing no harm.

CASE III.—*Puerperal Malarial Fever*.—Mrs. H., American, aged twenty-three; first pregnancy. Is a slight, delicate woman, with a phthisical history in maternal ancestry for generations back. She ceased menstruating early in August, and expected delivery early in May. Throughout gestation vomited constantly, and suffered considerably from attacks of sick headache that have been a source of great trouble to her for years. Has become emaciated and anemic, with slight cough. Urine: specific gravity, 1.015; acid, eight per cent. albumin, quantity large. Living in an intensely malarial neighborhood on the east side of this city. She had paroxysms of intermittent at six and three weeks previous to labor setting in. Quinine was prescribed, but taken irregularly.

May 4th.—Labor began about 10 p. m. last night. At 7 a. m. this morning pains expulsive, strong, and frequent. Head in the left occipito-anterior position. Membranes ruptured spontaneously. At 10 a. m. she was delivered of a live female child, weighing six pounds. Placenta readily extracted. Afternoon temperature, 102.5° F.; pulse, 106 (see chart).

5th.—Recurrence of fever in the afternoon; also on the 6th, though not so high. Ordered grs. v quinine every six hours. Otherwise feeling comfortable.

7th.—Severe and prolonged rigor this morning, followed by high fever and pulse. Five stools, due to magnesia taken early in the morning. Appearance of milk to-day. To take half a drachm of quinine in twenty-four hours.

8th and 9th.—Cinchonized and nauseated; otherwise feeling well, and taking nourishment.

10th.—High temperature to-night, with pain in left side of chest, and dyspnoea. Careful physical examination negative. Later, sweats profusely. Ice to head, quinine and stimulants.

11th.—Felt cold all the morning; also weak, tired, and sore. Nauseated, and vomiting. Kept cinchonized by 15 grs. quinine every six hours (or a drachm in the twenty-four) *per rectum*. Milk punch *ad libitum*.

13th.—Feeling better. No fever. Respiration 20. Professor Thomson in consultation. Symptoms pronounced to be due solely to malarial poisoning, with no pelvic or parenchymatous trouble.

14th.—Slept well. Sat up out of bed. Little appetite. No fever. Quinine, a drachm in twenty-four hours *per rectum*.

15th.—Another severe paroxysm of cold stage; fever and sweating, with headache, nausea, vomiting, and great prostration.

16th.—Repetition of yesterday's events. Taking 75 grs. of quinine in twenty-four hours *per rectum*, with nourishment and stimulants. Continually vomiting. Quinine increased to 120 grs. in twenty-four hours (20 grs. every four hours).

17th.—Only a slight rise in the temperature to-day.

18th.—Repeated large doses of quinine to-day, and consequently in the evening our patient became so greatly prostrated that we stopped the quinine and administered enemata of brandy and ammonia. These measures brought on a favorable reaction, so that by the 20th our patient was feeling bright and lively, with pulse and temperature normal, good appetite, no vomiting, and taking no medicine. From this date on improvement continued, and convalescence progressed to restored health. Ten grains of quinine were administered by enema, night and morning, to prevent any relapse, for a short time after permanent improvement began.

The two interesting points in the above-narrated case are as regards diagnosis and treatment. Regarding the first point I will premise by saying that only symptoms that were actually present are mentioned. All other symptoms and physical signs were carefully sought after by my friend Dr. W. A. James, who was associated with me throughout the management of the case, Professor Thomson, and myself, so as certainly to exclude septicæmia, puerperal fever, inflammatory fever, tuberculosis, and all other complications, no matter how remote, of the puerperium. At no time could any abnormal condition be made out regarding the generative organs or the lochia, all behaving as they would under ordinary circumstances. Finally, when one views the history previous to labor and the subsequent symptoms presented, no other diagnosis can be reached. The treatment may be said to have been heroic, but was urgently called for, as on the 15th it was thought the termination of the case would be fatal, and the experience of others with this disease, which we diligently examined, taught us was necessary. Warburg's tincture was administered, but not retained, and consequently had to be abandoned, and we were thrown back exclusively to quinine as the only weapon to combat this disease with.

THE LESSER DEGREES OF CHRONIC PELVIC INFLAMMATION IN WOMEN.*

By FRANK P. FOSTER, M.D.

By the expression "lesser degrees" I mean to imply those forms of the affection in which no history of an acute beginning can be elicited, or any sign that there has ever been a tendency to suppuration, and in which there is no bulky exudate. Negative as the terms are by which such cases are to be distinguished from those of which the immediate symptoms are ordinarily graver, and the physical signs more pronounced, the cases themselves are by no means of trifling significance; they are exceedingly common in occurrence, they are apt to be followed by consequences which produce serious impairment of the health, and they constitute an important element to be considered when we have to decide upon measures of treatment. A few words, therefore, with regard to each of these three aspects of moderate degrees of chronic pelvic inflammation in women may serve to call forth the discussion which this short paper is chiefly intended to give rise to.

We all know the frequency with which evidences of pleurisy are found in the bodies of persons who, during life, never suspected themselves to be the subjects of any thoracic trouble whatever. Perhaps it would be too strong a statement to say that like affections of the pelvic peritonæum, or of the cellular tissue between its folds, were equally common, or that they so often passed unrecognized. I think, however, that this much may be said: that they are by far the most frequent of all the diseases peculiar to women, occupying the position in gynecology that the various forms of eczema hold in dermatology. At least, that is the conviction I have been forced to, without the opportunity of supplementing clinical study by post-mortem investigation. If those of you who have devoted much attention to the practical study of general pathology have been led to a different conclusion, I trust that you will state the fact, for it will serve to correct the error into which it will show me to have fallen. It will be understood, of course, that I refer to women who have not only reached adult life, but passed a considerable portion of the usual child-bearing period.

Assuming, as you will allow me to assume for the time being, that I have truthfully stated the frequency of the affections under consideration, it becomes a matter of importance to inquire into the causes of this frequency. The periodical turgescence of the ovaries and the uterus inseparable from the menstrual function suggests itself at the outset, as, indeed, it has suggested itself from time immemorial, as an ætiological factor. The idea is obvious and plausible, and it can not be denied that obviousness and plausibility often give the clew to facts. On the other hand, menstruation is a natural process, and, while it is true that in many instances our organs perform their functions at the risk of injury to their integrity, if we allow a preponderating sig-

nificance to the monthly pelvic congestion of menstruation, we must admit that that function is exceptionally prone to be followed by damage to the parts concerned—an admission which, to be of any great force, ought to be sustained by more exact data than those now at our command. Without specific facts, however, it would be quite as irrational to deny the morbid action of menstrual congestion as to cling to it to the exclusion of more precise ideas. But perhaps the present state of our knowledge warrants some such statement as this: that menstrual congestion is probably insufficient of itself to initiate a morbid process, although abundantly capable, by its repeated occurrence, of stimulating and developing diseased conditions which, but for some perturbation of the sort, would generally tend to disappear spontaneously. In other words, and limiting the statement to normal menstruation—to the element of congestion—the performance of that function is not a cause of disease, strictly speaking. Any marked deviation from the normal course of menstruation presupposes some antecedent disease, and, that granted, the question of the primary ætiological significance of menstruation is answered.

Abnormalities of gestation and parturition, being in themselves pathological, we can more readily admit to be capable of giving rise to positive disease of the pelvic structures. To enter upon a discussion of their importance, however, would be to go over a field familiar to you all. I shall, therefore, content myself with suggesting one or two other possible sources of pelvic inflammatory disease that have come to my notice. In a certain proportion of cases—not, I must admit, a large proportion—a coincidence may be traced between the first manifestations of the disease and an attack of some intestinal trouble of an inflammatory nature. In quite a number of instances I have thought there was reason to associate an attack of dysentery with the production of the sort of disease under consideration. In still others, fewer in number, typhoid fever has seemed to play the same part. Doubtless the connection between intestinal affections and pelvic inflammation is no new notion, but it may be, nevertheless, that it is not borne in mind so much as the facts would seem to call for.

Leaving the matter of ætiology, the pathogenetic importance of slight forms of pelvic inflammation is to be considered. It is my decided conviction that this feature of these affections is underrated by many gynecological writers. Indeed, with the exception of Dr. Emmet in this country and B. S. Schultze in Germany, I know of no author who gives it what I consider due prominence. Chapter after chapter is devoted to displacements of the uterus, to flexions of that organ, to dysmenorrhœa, to endometritis, and even to sterility, while the affections now under consideration—in my opinion, the most common beginning of them all—are treated as of minor consequence.

Not to take up your time with an enumeration of the various disorders ordinarily called "uterine" which may be due to antecedent non-visceral inflammation, I will only call your attention to the capabilities of contracting layers and small masses of exudate in distorting the uterus, in binding it in abnormal attitudes and situations, and in preventing its expansion under the engorgement of menstruation; in

* Read before the New York Clinical Society, January 25, 1884.

producing stenosis of the Fallopian tubes; in crippling the ovary; in destroying the free expansion and contraction of the bladder; and in interfering with the return of the venous blood from all these organs. This one element seems to me ample to account for the great majority of cases of dysmenorrhœa, sterility, ovarian pain, profuse menstruation, and leucorrhœa that make up so large a share of the every-day practice of gynecology.

It is not my purpose in this paper to enter upon the consideration of specific measures of treatment, but, if the foregoing views are of any value, they should not fail to exert a far-reaching influence upon the treatment of many of the diseases of the sexual apparatus not generally suspected to be connected with extra-uterine inflammation and its products. Excluding the neoplasms that threaten life, I should say that, whatever abnormal conditions may be found affecting the organs in question, so long as chronic extra-uterine inflammation co-exists, it should be looked upon as the most important feature in the case, and as the one to which treatment ought chiefly to be directed. So far as my own experience goes, I have met with far more success by following this course than by seeking to remedy the more obvious derangements, whether versions, flexions, hæmorrhages, discharges, stenoses, or any of the other conditions that are usually the direct source of complaint. If I stood altogether alone in these views, I should hesitate to put them forward as of any importance, but I may be permitted to say that for several years past Dr. Emmet has virtually given up intra-uterine medication in the treatment of endometritis; operations designed to enlarge and straighten the uterine canal are falling into disuse; the flexion theory of dysmenorrhœa is drawing to its downfall; and it is beginning to be felt that the curette is not all-powerful.

But it is not alone the useless from which these considerations should warn us to desist; some of the therapeutic measures that have been much resorted to are injurious, especially when there is a tendency for the slumbering inflammation of the serous and cellular structures of the pelvis to break out into an acute affection. I will mention only that one of them which is probably considered by many the one least likely to cause trouble—the operation of replacing the uterus by means of an instrument. I doubt if there are many who will agree with me in the statement that this procedure is unwarrantable under all circumstances, but that is my firm conviction. The leverage afforded by an instrument like the sound passed into the uterus, to a certain extent unguided and unrestrained by the sense of touch, is certainly capable of doing much damage. The danger would not be so great if the instrument were used only by those who appreciate the importance of extra-uterine inflammation, and are capable of recognizing its existence in the class of cases referred to, but there seems to be a mania for instrumental interference among those whose knowledge of the pathology and diagnosis of pelvic diseases is very limited. It is to be hoped that this state of things will pass away when gynecology takes its place on the plane reached by the other practical branches of medicine.

Book Notices.

The Diagnosis and Treatment of Diseases of the Ear. By OREN D. POMEROY, M. D., Surgeon to the Manhattan Eye and Ear Hospital, etc. With one hundred illustrations. New York: Berningham & Co., 1883. Pp. 392. [Price, \$3.]

This book is expressly designed for the general practitioner, and hence the subject is discussed from the practical rather than from the scientific standpoint. Allowing for that fact, we still think it is to be regretted that some account of the anatomy and physiology of the organ of hearing has not been included.

The work embraces six main divisions, which treat of the different diseases of the various parts of the auditory apparatus, and three additional ones, which describe the instruments used in examining and treating the ear, the throat, and the nares, with hints as to methods of examination and as to artificial aids to hearing. The first of the main divisions treats of the diseases of the auricle, and considerable space is given to the subject of perichondritis auriculæ and its treatment, the author advising against the use of the knife unless fluctuation is decided and there appears to be a pus cavity of considerable size. The next section treats of diseases of the external auditory canal, and explicit and sensible directions are given for the removal of foreign bodies from the canal. Considerable attention is given to the management of impacted cerumen and to its consequences. The author highly recommends the flanged ear-syringe devised by himself, not only for removing foreign bodies, but also in the treatment of purulent inflammations of the middle ear. The section on exostoses and hyperostoses of the external canal is good, especially in regard to operative treatment.

The sections on the diseases of the middle ear and the mastoid region are full and well written, the author's views being mainly in accord with those of most modern otologists, and some good points are made concerning the ætiology of catarrhal affections and their combined constitutional and local treatment. Dr. Pomeroy prefers the syringe in the treatment of chronic purulent inflammation of the middle ear, although he admits that the "dry treatment" sometimes gives good results. He recommends the employment of the faucal catheter devised by himself, both as a means of inflation and for the purpose of making astringent and caustic applications to the naso-pharynx and to the mouth of the Eustachian tube. He prefers the forceps to the snare for the removal of aural polypi. In the treatment of mastoid affections, he gives the preference to the use of Buck's drills over all other means of opening the mastoid process. Malignant and syphilitic disease of the ear and boiler-makers' deafness are discussed in short sections, and a number of interesting cases are reported, showing the course of each disease and the effects of treatment. There is a brief but interesting section on disease of the labyrinth dependent on middle-ear disease, with another on disease of the acoustic nerve and labyrinth dependent on affections of the brain and its membranes.

The work is perhaps well enough illustrated on the whole, but a number of the woodcuts are bad and entirely unworthy of the subject-matter of the book, especially those representing pathological appearances. The student and the general practitioner may safely refer to Dr. Pomeroy's work as a trustworthy guide to the diagnosis and treatment of diseases of the ear, drawn as it has been from the personal observation and experience of such a well-known and careful observer as the author is recognized to be.

The Lettsoman Lectures on the Treatment of some of the Forms of Valvular Disease of the Heart. Delivered before the Medical Society of London. By A. ERNEST SANSON, M. D. Lond., F. R. C. P., Physician to the London Hospital, etc. Philadelphia: P. Blakiston, Son & Co., 1883. Pp. 93. [Price, \$1.25.]

THE expectations entertained by those who have read Dr. Sansom's previous writings on diseases of the heart will not be disappointed by this little book. The first of the three lectures is devoted to the general consideration of endocarditis, its morbid anatomy, and the present methods of treating it. The second is given to mitral regurgitation. The author seems to have great confidence in remedial measures for the relief of this condition, and enumerates drugs in the order of their usefulness as follows: Digitalis, belladonna, casca, caffeine, *Convallaria maialis*, morphine, and alkalies. He gives more prominence to morphine and belladonna than is usual with authors, and in this we are heartily in accord with him, for, when judiciously given, there are no better remedies for certain forms of heart disease.

The third lecture deals with the diagnosis and treatment of mitral stenosis. Digitalis the author thinks of much less use in this condition than in regurgitation, and he relies more on caffeine and convallaria. His suggestions as to treatment are admirable in the main, but it seems to us that he has not laid sufficient stress on the management of the remote effects of cardiac disease, especially those on the gastro-intestinal tract in mitral stenosis. To be sure, these matters do not belong directly to his subject, but indirectly they are of great importance. We often fail to produce on the heart certain effects which the drugs employed ought to cause, simply because we have overlooked some abnormal condition of the stomach.

We quite agree with Dr. Sansom that venesection may be useful in certain conditions of cardiac disease, and consider the suggestion a timely one. Every general practitioner will find it profitable to read this little book.

BOOKS AND PAMPHLETS RECEIVED.

Student's Manual of Electro-Therapeutics, embodying Lectures delivered in the Course on Therapeutics at the Woman's Medical College of the New York Infirmary. By R. W. AMIDON, A. M., M. D., etc. New York: G. P. Putnam's Sons, 1884. Pp. v-93.

The Extra Pharmacopœia of Unofficial Drugs, etc. By WILLIAM MARTINDALE, F. C. S., etc., and W. WYNN WESTCOTT, M. B. Lond., etc. Third Edition. London: H. K. Lewis, 1884. Pp. vi-330.

Hay Fever; its Ætiology and Treatment. A Lecture delivered at the London Hospital Medical College. By MORELL MACKENZIE, M. D. Lond., Lecturer on Diseases of the Throat, and formerly Physician to the Hospital, etc. London: J. & A. Churchill, 1884. Pp. 24. [Reprint from the "British Medical Journal." Price, 1s.]

Notes on Labor in Central Africa. By ROBERT W. FELKIN, F. R. S. E., F. R. G. S., etc. [Reprint from the "Edinburgh Medical Journal."]

A Paper on Extirpation of the Entire Tongue for Cancerous Affections. Read by BASIL NORRIS, M. D., Surgeon, U. S. A., before the American Surgical Association, Washington, D. C., 1884.

Annual Announcement of Trinity Medical School, Toronto, Session, 1884-'85.

The Cholera and Science. [Reprints from "Science."]

Treasury Department. Report on the Internal Commerce of the United States. By JOSEPH NIMMO, JR., Chief of the Bureau of Statistics. For the Fiscal Year 1881-'82. Commerce

and Navigation. Washington: Government Printing Office, 1884. Pp. vii-39.

Annual Announcement of the American Veterinary College. Session of 1884-'85.

The Treatment of Backward Displacements of the Uterus and of Prolapsus Uteri by the New Method of Shortening the Round Ligaments. By WILLIAM ALEXANDER, M. D., etc., Visiting Surgeon to the Liverpool Parish Infirmary. London: J. & A. Churchill, 1884. Pp. 71.

Health Hints for Travelers. By JOHN C. SUNDBERG, M. D. Philadelphia: D. G. Brinton, 1884. Pp. 61.

Minutes of the State Medical Society of Arkansas, at its Ninth Annual Session.

London Water Supply. Report, etc., No. xxxix.

Address on Practical Medicine. By JOHN V. SHOEMAKER, A. M., M. D., Chairman of the Section of Practice, etc. Delivered before the American Medical Association, at the Thirty-fourth Annual Meeting, held at Washington, D. C., May 7, 1884. Philadelphia, 1884.

On Paroxysmal Fever—not Malarial. By J. H. MUSSEY, M. D., etc. [Reprint from the "Proceedings of the Philadelphia County Medical Society."]

A Modification of the Sphygmograph, being a Change in the Base of the Instrument of POND. By J. H. MUSSEY, M. D., etc. [Reprint from the "Medical and Surgical Reporter."]

Nineteenth Annual Announcement of the Medical Department of the Willamette University, Portland, Oregon. Session of 1884-'85.

Sixth Annual Announcement of the Fort Wayne College of Medicine. Session of 1884-'85.

The Essentials of Anatomy, Physiology, and Hygiene. A Text-Book for Schools and Academies. By ROGER S. TRACY, M. D., Sanitary Inspector of the New York City Health Department, etc. New York: D. Appleton & Co., 1884. Pp. xii-299, [Appletons' Science Text-Books.]

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & Co.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JULY 5, 1884.

CIVIL PRACTICE BY ARMY SURGEONS.

IN our issue for June 14th we made a few remarks of a general nature on this subject, the occasion of our doing so being a newspaper attack on the medical officer stationed at Fort Trumbull, in Connecticut. The attack was petty and narrow in the extreme. In so far as it had any point worth noticing, it was the assumption, in effect, that it was an offense, or at least an act of injustice, for army surgeons to practice medicine among civilians; but this was backed up by an unspeakably vulgar appeal to the dislike entertained by mean and ignorant people toward persons who draw pay from the Government, the writer even going so far as to descant upon the munificence of the army surgeon's emoluments. All this was, of course, the veriest demagogism, and we declined, and still decline, to entertain the thought of its having been inspired by the medical profession of New London.

We have lately received an anonymous letter, apparently sent with the idea that we would publish it, suggesting that our remarks were unjust to the New London physicians, and criticising the course alleged to have been followed by the medical officer at Fort Trumbull. The letter can not appear in our columns, except with its author's signature, for we think it unbecoming to publish injurious criticisms of individuals anonymously; besides that, we never publish a letter of any sort unless we know the writer's name and address. We have, therefore, at present nothing further to say of the New London affair than that, if it is to be made the subject of controversy, the discussion had better be carried on in the recognized channels of professional opinion than in the local newspapers.

As to the general question, divested of casual complications, it seems to us that there are only two objections that can possibly be brought against the propriety of private practice on the part of army medical officers. One of them concerns the relations of those officers to the Government, and, unless we are mistaken, the War Department has rendered decisions to the effect that the practice is allowable. Our impression is, too, that the Department feels it to be not only allowable but desirable in the interest of the service, and for that feeling there appears to be ample ground. In the first place, the prospect of an income in addition to the official pay undoubtedly serves to attract men to the service who would otherwise feel the sacrifice too great for them to make. In the second place, the mere fact of being to a certain extent engaged in general practice makes a man a better medical officer—it lifts him out of the grooves of routine, sharpens his wits by contact with his civilian *confrères*, and inspires his military practice with an interest

quite above and beyond the mere idea of performing his official duty in such a way as not to incur the censure of his superiors.

The other of the two conceivable objections has reference to the medical officer's duty toward his professional brethren in civil life. Any consideration of this aspect of the matter by interested persons is likely to be complicated by side-issues, and it may certainly be conceded that there is often as much in the way in which a thing is done as in the nature of the act itself. But into these casual details it has not been our purpose to enter. The broad question is one that has exercised the profession at various times, and is even now the subject of lively discussion in France. Our own position is that no argument above the level of trades-unionism can be brought forward in support of the objection.

No doubt competition with an advantage is sometimes a hardship, but it is not necessarily an injustice, and, practically, the particular hardship encountered in the competition of a fellow-practitioner with the advantage of an official position of honor, and one that guarantees his capability to the public, must be much mitigated by the counter-advantage of permanent residence. We can scarcely suppose that the better-paying class of citizens often choose a medical officer of the army for their family physician, except on the outposts of civilization, for they are not given to changing their physicians on slight occasion, and they are aware that an army surgeon is liable to be ordered away at any time. The case is somewhat different, of course, in the city of Washington, where medical officers of high rank, have positions that may be called practically permanent, but it should be borne in mind that these few men have attained to their positions only after long terms of service, as a rule, and surely the reward of their maturer years is not grudged them by their brethren in civil life.

CHRONIC ALCOHOL POISONING.

Second Article.

THE report of which we began a summary last week deals next with the effects of alcohol on the nervous system in the animals that were subjected to experiment. The phenomena of excitement were not observed, but, so soon as the hogs had swallowed their spirituous allowance, they lapsed into a state of torpor which lasted for several hours. After the experiments had been continued a number of months, muscular tremors were produced, with weakness of the limbs, particularly the posterior extremities. A slight push was sufficient to throw the animals to the ground, and, when they were once down, it was with great difficulty that they were able to rise to their feet again. No lesions of the nervous centers were discovered post mortem. M. Dujardin-Beaumetz thinks that the differences in the psychological phenomena of alcoholism in the hog and in man are to be imputed to the small size of the brain in the former. In the hog, alcoholic poisoning produces somnolence, prostration, and hebetude, but there is nothing of the delirium and fury of human drunkenness.

With regard to the effects of chronic alcoholism on nutrition, the French experimenters found that the animals continued to

grow fat under their daily rations of spirits; but, whenever intestinal troubles supervened, especially if they persisted for some length of time, the appetite declined and emaciation ensued. After two years of subjection to the alcoholic regimen, all the animals became lean and continued to lose flesh, although a sufficiency of food was allowed them. Their muscular tissue did not present a healthy appearance, interstitial hemorrhages were noted in a number of them, and all the carcasses were condemned by the official inspectors.

As for the influence exerted by the different alcohols, it was found, as had been determined by previous experimenters, that the most toxic and deleterious of the ardent spirits employed were those that contained certain other alcohols besides ethyl alcohol. The purified products of the distillation of wine were by far the least noxious, both in immediate and in remote effects. As is well known, the alcohol of such liquors is chiefly that of the ethyl series. The presence of certain quantities of propyl, amanthyl, capryl, and amyl alcohols in the spirits ordinarily used accounts for their great intoxicating power as compared with brandy. It is especially the spirits obtained from grains, beets, and potatoes that contain the most amyl, butyl, and propyl alcohols, and drunkenness is at its maximum in those countries, such as the Scandinavian, where those products are most used. Those animals to which the impure, coarse, unrectified products of the still were given showed the earliest, the most protracted, and the severest interference with their organs and functions. A hog that had unrectified grain spirit succumbed in less than two years; one that got beet whisky had pronounced congestion of the digestive tube, the liver, and the lungs, and atheroma of the aorta; and one that took potato spirit presented hepatic congestion of the most decided grade. On the contrary, those that were dosed with purified ethyl alcohol, potato spirit ten times rectified, or other rectified alcohols, showed few lesions or none at all—a fact in striking accord with the national experience alluded to. The hogs that were given essence of absinth showed a peculiar nervous excitation, tremors of the limbs, contractures, and cutaneous hyperæsthesia—but a slight touch was needed to provoke violent spasms of the limbs.

The results of these thirty or more months' careful experiment should help to a more scientific understanding of the subject of chronic alcohol poisoning, and among the practical hints to be drawn from them is the question whether it would not be well for the State to offer some substantial encouragement to the better rectification and purification of the liquors of commerce. Certainly something might be done, even in this way, to stay the evils of intemperance, which governments have sought—confessedly, with scant success—to arrest by prohibitory legislation.

The crude products of many hundreds of distilleries are being distributed over the land, loaded with fusel oil and other fiery and destructive substances, and are working widespread mischief and devastation.

MINOR PARAGRAPHS.

THE GROSS PROFESSORSHIP OF PATHOLOGICAL ANATOMY.

It is gratifying to observe the progress already made in the work of raising an endowment fund for the establishment of the memorial professorship to be designated in honor of the late Professor Gross. We wish the Alumni Association of the Jefferson Medical College all possible success in their praiseworthy undertaking, and we are glad to see abundant indications that the work of contributing to the fund will not be confined to the graduates of the school. It is in the highest degree fitting that they should have proposed the movement, and that they should assume its management, but the whole profession in America should esteem it a privilege to take part in furnishing the means. Contributions, which may be sent to Dr. R. J. Dunglison, Lock-box 1,274, Philadelphia, will be acknowledged in the "Medical News," of that city.

THE OHIO RIVER FLOOD SUFFERERS.

WE are indebted to Dr. R. P. M. Ames, an officer of the Marine Hospital Service, stationed at Evansville, Indiana, for a copy of the official report made by him of the relief measures afforded on two trips of the relief boat Carrie Caldwell. Apart from the sanitary aspects of such calamities as overtook the people in the district affected by the flood, the report of Dr. Ames affords gratifying evidence of the diverse ways in which the Marine Hospital Service extends its beneficent action under its present management.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 1, 1884:

DISEASES.	Week ending June 24.		Week ending July 1.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid	6	2	4	0
Typhoid Fever	12	5	16	4
Scarlet Fever	54	16	38	15
Cerebro-spinal meningitis	6	5	3	3
Measles	181	33	171	30
Diphtheria	38	16	43	23

Yellow Fever.—Twenty-five deaths from the disease are reported to have taken place in Havana during the week ending June 28th. Last week the citizens of Benson, A. T., were reported to have sent a petition to the Surgeon-General of the Marine-Hospital Service asking for the establishment of a quarantine station at Nogales, to guard against the introduction of yellow fever from the infected districts on the western coast of Mexico.

Cholera in Europe.—The outbreak at Toulon, mentioned in our last issue, has become unmistakably epidemic during the past week, and has spread to Marseilles, at which port the sanitary authorities very properly decline to issue clean bills of health to outgoing vessels. Two cases are also reported from Saluzzo, in northern Italy. The daily number of deaths from the disease in Toulon is stated as from eight to ten. M. Brouardel and M. Proust, who are studying the outbreak by order of the French Government, are said to have come to the conclusion that the disease is really Asiatic cholera, although of a mild type. It is reported that Dr. Koch will offer his services in investigating the nature of the outbreak. France and the neighboring countries seem to be taking all possible precautions to check the spread of the disease. Arrangements are being made for fumigating passengers and merchandise at the Paris railway

stations. At Gibraltar, where some hesitation appears to have been felt at first, it has finally been decided to quarantine vessels arriving from French Mediterranean ports. A like course has been entered upon by Spain, Turkey, Austria, and Italy, and at Odessa vessels from China or India are to be detained twenty-four hours for observation, and two weeks if they are not provided with clean bills of health. Spain, being dissatisfied with the course pursued by England, will quarantine all vessels from that country. Besides these maritime quarantines, the Spanish Government has established a sanitary cordon along the French frontier, the Italians are subjecting overland passengers from France to a detention of five days, and Austro-Hungary is about to take measures to the same intent. The need of vigilance is equally recognized on this side of the Atlantic. On Monday the Surgeon-General of the Marine-Hospital Service recommended to the Secretary of the Treasury that an appropriation be asked for providing for the appointment of inspectors at American consulates at foreign ports, to be charged with sending information of the departure of emigrants and merchandise from infected districts. This recommendation, having been approved by the Secretary, has gone to the Senate Committee on Appropriations. On the same day a rather wild proposition was introduced into the House appropriating \$200,000 to be expended by the National Board of Health in preventing the introduction and spread of the disease in this country. On Thursday of last week the Health Officer of the Port of New York published the following notice: "Masters of vessels and pilots will please observe that, on and after June 30th, all vessels arriving from the following ports will be boarded and examined from the quarantine ship in the Lower Bay—viz.: All ports in the West Indies, Bahamas, Bermuda, Mexico, the Spanish Main, the East Coast of South America, and the West Coast of Africa; also all vessels from ports where cholera or yellow fever prevailed at the time of departure, or upon which cases of cholera or yellow fever have occurred during the passage." The Canadian Government has ordered the quarantining of all vessels from the infected French ports, whether arriving directly or after touching at other foreign ports.

Our Sanitary Representatives abroad this summer will include Dr. Alfred L. Carroll, the secretary of the Board of Health of the State of New York, and Dr. Woolsey Johnson, one of the commissioners of the Health Department of the city of New York.

An Italian Hospital has been opened in London, and we learn from the "Gazzetta degli Ospitali" that persons of all nationalities will be admitted, as well as of all religions and all shades of political opinion.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 22, 1884, to June 28, 1884:*

CLEMENTS, BENNETT A., Major and Surgeon. Ordered to relieve Major Joseph P. Wright, surgeon, of his duties as attending surgeon at the Leavenworth Military Prison, Fort Leavenworth, Kansas. Major Wright, on being relieved, ordered to report to the commanding general, Department of Texas, for assignment to duty. Par. 7, S. O. 144, A. G. O., June 21, 1884.

DICKSON, JOHN M., Captain and Assistant Surgeon. Assigned to duty as Post Surgeon, Alcatraz Island, California. Par. 3, S. O. 71, Headquarters Department of California, June 19, 1884.

GIRARD, A. C., Captain and Assistant Surgeon. Granted leave of absence for six months, with permission to go beyond sea. Par. 11, S. O. 148, A. G. O., June 26, 1884.

Society Meetings for the Coming Week:

TUESDAY, *July 8th:* Medical Societies of the Counties of Chautauqua (annual). Clinton, Jefferson, Madison (annual), Oneida (annual), Ontario (annual), Rensselaer, Schuyler, Tioga, Ulster, and Wayne (annual), N. Y.

WEDNESDAY, *July 9th:* Medical Societies of the Counties of Cayuga and Seneca (annual), N. Y.; Tri-States (New York, Pennsylvania, and New Jersey) Medical Association (Port Jervis, N. Y.).

THURSDAY, *July 10th:* Brooklyn Pathological Society; Medical Society of the County of Fulton, N. Y.

FRIDAY, *July 11th:* Medical Society of the Town of Saugerties, N. Y.

OBITUARY NOTES.

Dr. William Sutton.—Dr. Sutton, who had retired from practice, died on Friday, the 20th inst. He was of English birth, and came to America about thirty-five years ago. For several years he served as one of the board of surgeons to the New York Police Department. He was seventy years old at the time of his death.

Dr. Joel Foster.—Dr. Foster died on Sunday, June 29th, at the age of eighty-two years, as the result of an acute illness attended with jaundice. Up to within a few weeks of his death he continued in the busy practice of medicine. Dr. Foster was a native of Vermont, and was graduated in medicine at the Jefferson Medical College, of Philadelphia, in the year 1826. He began practice in Schoharie County, and came to New York in 1835, where for many years he did a large and laborious practice. He was one of the original members of the Academy of Medicine, and a member of the Medical Society of the County of New York, of the Medical Society of the State of New York, of the Physicians' Mutual Aid Association, of the Society for the Relief of Widows and Orphans of Medical Men, and of the New York County Medical Association. He was one of the founders of the New York Infant Asylum, of which he was the honorary president at the time of his death. The demands of Dr. Foster's life allowed him but little opportunity to contribute to the literature of the profession, but he was a devoted student in microscopical research.

Dr. Charles H. Rawson, of Des Moines, Iowa.—Dr. Rawson died on Friday of last week, at the age of fifty-six years. He was born in Vermont, and was a graduate of the Bellevue Hospital Medical College. Early in his professional career he was a surgeon in the service of the Pacific Mail Steamship Company, and was afterward connected with the United States Marine Hospital at San Francisco. He settled in Des Moines in 1856, and served as surgeon of an Iowa regiment during the civil war.

Letters to the Editor.

ANOTHER CASE OF ZOSTER FOLLOWING TRAUMATISM.

IMLAYSTOWN, N. J., June 23, 1884.

To the Editor of the New York Medical Journal:

SIR: Seeing in the journal for last week the report of a case of zoster following an injury, I thought it might be of interest to record a similar case recently under my care. A lady, aged sixty-five, of good general health, tripped and fell down three steps leading from one room to another, striking upon her forehead. The pain was not very severe at the time, and soon

passed off. Two days after, she sent for me on account of what I took to be neuralgia of the first division of the fifth nerve, for which I prescribed, but without much effect. After three days more, an herpetic eruption appeared, followed for several days by additional clusters of vesicles, which ceased to break out simultaneously with the disappearance of the pain. The pain and eruption were entirely confined to the area supplied by the right ophthalmic nerve. In three weeks from the receipt of the injury the eruption had entirely disappeared. The treatment consisted of saline ferruginous laxatives and soothing applications.

Very respectfully,

H. G. NORTON, M. D.

Proceedings of Societies.

CHICAGO MEDICAL SOCIETY.

Meeting of June 16, 1884.

The Significance of Jaundice in Diagnosis.—Dr. W. E.

QUINE read a paper in which, after alluding to the various theories that had been advanced in explanation of the obstructive and the non-obstructive varieties of jaundice, he pointed out that the attendant symptoms were mostly due to the presence of colorless bile acids, the bile pigment being harmless. Cerebral disturbance due to hepatic derangement, and associated with cholemia, was not caused by the presence of normal bile, but by different though unexplained species of toxæmia. Slight jaundice was often overlooked, and in some instances could not be distinguished from the cachexiæ, except by the discovery of bile acids in the urine; so that the diagnosis usually turned upon the discovery of the cause, and not upon the mere recognition of the effect. Jaundice coming on suddenly during apparent health, and without pain, was usually of emotional origin and transitory. When it depended on disease or injury of the brain, acute atrophy of the liver, snake-bite, or an infectious fever, it was always associated with mental disturbance. If it was attended with fever, and was well marked, it was secondary to inflammation of the biliary passages, pneumonia, toxæmia, or infective inflammation of the portal vein. If it came on suddenly, and was preceded by paroxysmal pain and vomiting, it was caused, nine times out of ten, by biliary calculi. If it was preceded by typical symptoms of gastro-duodenitis, it was obviously of catarrhal origin. Impassable obstruction of the common bile-duct was shown by jaundice of great intensity, by clay-colored stools, and, in recent cases, by distension of the gall-bladder. Jaundice caused by sudden obstruction of the biliary passages was always associated with paroxysmal pain and nausea, but there was no means of ascertaining the nature of the obstructing body except its discovery in the stools. In the rare cases of sudden obstruction by cancerous, hydatid, or aneurysmal tumors, there was almost always a history of impaired health, enlargement and deformity of the liver, ascites, etc., which, together with physical exploration, would lead to a correct diagnosis. A sudden return of the natural color of the faces would confirm a diagnosis of obstruction. Occlusion of the cystic duct might be attended with as much pain, nausea, and distension of the gall-bladder as occlusion of the common duct, but there would be no jaundice. In occlusion of the hepatic duct the same symptoms were present, including jaundice, and excluding distension of the gall-bladder. It was impossible to distinguish between occlusion of the hepatic and occlusion of the common duct, but the former was rare, because the duct

increased in size from above downward. If jaundice persisted after the symptoms of biliary colic, or of catarrhal inflammation, had disappeared for a month, or if jaundice, having subsided after a biliary colic, returned slowly and without pain, it might be assumed that stricture of the duct had resulted, from inflammatory thickening, from adhesion of its walls, or from the cicatrization of an ulcer. Repeated attacks pointed to gall-stones. If jaundice came on slowly, without antecedent colic or catarrh, and without evidence of impaired health or of portal obstruction, it was probably caused either by pressure upon the duct or by the growth of a tumor within its walls. When the body producing the pressure was large enough, it might readily be appreciated, as in the case of pregnancy, ovarian tumor, aneurysm, distension of the colon, etc.; but, when it was small, or constituted by enlargement of lymphatics in the fissure of the liver, it was apt to escape detection. Slight but persistent jaundice might be due to incomplete occlusion of the common duct or to complete occlusion of a branch of the hepatic, but usually it was found associated either with valvular disease of the heart, with some disease of the lungs which obstructed the circulation, or with cirrhosis of the liver. If ascites co-existed, the disease was either cirrhosis or cancer of the liver; if the liver was abnormally small, it was cirrhosis, and, if it was too large, it was either hypertrophic cirrhosis or cancer, and the differentiation between the two was seldom attended with difficulty. Absence of jaundice did not imply absence of hepatic disease, since the liver might be destroyed by disease, or extirpated by operation, without jaundice ensuing. Jaundice was not a prominent symptom of hepatitis, if we rigidly excluded catarrhal inflammation of the biliary passages. Neither was it a feature of hepatic abscess, in which, at most, a mere muddiness of the complexion was usually seen. These affections were rare in temperate latitudes, and, when encountered, were generally found to be secondary to direct injury of the liver or to infective inflammation of the portal vein. Jaundice was not a symptom of waxy or of fatty liver, or of hydatids, except as an extraordinary complication.

Dr. G. C. PAOLI thought there was no doubt that jaundice often escaped recognition in cases of disease. In scirrhus of the liver there might be only very slight pigmentation, and no pain, and we could not diagnosticate the disease in its early stages. In some affections there might be yellowness of the conjunctiva, and yet we might regard it as trivial, and the same might be said of slight jaundice accompanying some serious maladies. In fever with icterus, in a few weeks—perhaps three—there would be clay-colored stools, but without organic affection of any of the vital organs.

Dr. S. H. STEVENSON asked the author of the paper if it was the cholesterin that gave rise to toxic or cerebral disturbance in cases of obstructed bile-ducts.

Dr. J. J. M. ANGEAR questioned the adequacy of any of the theories that were held to explain the connection between the pigmentation of the skin, the state of the biliary function, and the symptoms.

Dr. A. R. JACKSON admired the compactness of the paper; it was a model to be emulated, giving just what was wanted, stripped of verbiage.

Dr. J. H. ETHERIDGE alluded to the diversity of coloring matters in pigmentary substances and to the complicated relations of vascular and nervous derangement in the production of jaundice in many cases.

Dr. C. T. FENN asked what it was that gave rise to a jaundiced condition of the skin after death in cases where death was due to hepatitis.

Dr. QUINE remarked that it had not been proved that bile was poisonous, or that cerebral symptoms followed as a result

of its presence in the blood; the blood and the secretions might be saturated with it for years and no cerebral disturbance ensue. He could not answer all the questions that had been put, nor could he say how the information was to be obtained. As to the occurrence of jaundice after death, alluded to by one of the speakers, he was not aware of the fact.

The Effect of Noise upon Certain Forms of Deafness.—

Dr. G. F. HAWLEY read a paper in which he remarked that, more than two hundred years ago, Dr. Thomas Willis, of Amsterdam, described a certain form of deafness in which the hearing was improved by noise. This symptom, termed *paracusis Willisii*, had been accepted by most aurists, but no satisfactory explanation of it had ever been given. While Politzer, von Trötsch, and others considered that it depended on some change in the position of the ossicles or of the *membrana tympani*, many, like Kramer, took the ground that it was due to a stimulation of the auditory nerve, which was thus forced to a more healthy action. [Experience favored the theory that the middle ear was the seat of the symptom, some change being brought about by the constant noise which restored the hearing for the time being. What this change was was still open to discussion, and it might be of interest if he related the following case, which had come under his observation when he was house surgeon at the Golden Square Hospital, in London:

Mrs. H., thirty years of age, had suffered for five years with marked deafness in both ears. She heard common conversation with difficulty except when there was a noise, but then her hearing appeared to be greatly improved. On the left side a watch could be heard only upon contact, and on the right side at a distance of two inches. A tuning-fork showed no trouble with the acoustic nerve, but clearly indicated some disturbance of the middle ear. The drumhead was normal as to tension, color, etc. There was perfect mobility of the malleo-incudal joint, and nothing indicated ankylosis of any of the tubes. The throat appeared healthy, and both Eustachian tubes were patent.

This case was a good example of the form of deafness under consideration. Roosa, however, mentioned two cases in which the drumhead was more or less destroyed, and yet noises improved the hearing. In both cases the ossicles were intact. Politzer, in his "Aural Surgery," stated that the improvement was seen only in middle-ear affections of an adhesive or sclerotic character, and regarded it as a most unfavorable symptom. Roosa, on the contrary, stated that it was found in many forms of ear disease, and did not necessarily prevent favorable results from treatment. In his article on "The Effects of Noises upon Diseased and Healthy Ears," he said: "I have known two cases where this symptom occurred in patients who regained their hearing perfectly. While the symptom frequently accompanies incurable disease of the middle ear, I believe it is a very frequent symptom in subacute cases where both ears are affected. Of course, it would not be observed in disease of one ear only." Whatever the cause of the symptom, that writer thought we were justified in believing that certain pathological changes were present in the middle ear which would be found at no other time. But in what did the change consist? Willis thought it was brought about by the action of strong sound-waves upon a relaxed *membrana tympani*. So long as the drumhead was relaxed, it refused to respond fully to wave-impressions—it was not a perfect conductor until its tension was restored. Noises, by forcing air against the membrane, pressed it inward and restored its tension for the time being. If the improvement was found only in such cases as Willis described, we might accept his theory, but, unfortunately, it was present when there was no change of the drumhead. There were two other elastic membranes in the middle ear, one of which took as important a part in conveying wave-impressions as the *membrana tympani*, and any change in it would be fully as disastrous

to hearing—he referred to the membrane of the *fenestra ovalis*. When we considered the extraordinarily fine shades of vibrations transmitted by this membrane to the fluids of the labyrinth, were we not justified in expecting that any loss of accuracy and precision in its action would cause a corresponding loss of hearing power? According to Riemann, the movements of the stapes in the fainter tones were so slight as to escape detection even with the highest power of the microscope; therefore a corresponding sensitiveness must be present in the membrane for the appreciation and transmission of these vibrations. If, then, the membrane became relaxed or lost its vibrating power from any cause, it would no longer act as a sound-conductor, but as a damper to wave-impressions. Not only must this elastic plate (so called by Politzer) be capable of responding fully to any wave-impulse, but it must also bear a certain relation to the foot of the stapes, *i. e.*, a due amount of pressure must be applied by the stirrup, and a sufficient resistance be offered, in every ear that possessed perfect hearing. A proof of this statement lay in the fact that, when deafness was caused by destruction of the drumhead, the incus, and the malleus, the hearing was frequently improved by an artificial drumhead, which pressed the loose stapes against the membrane of the *fenestra ovalis* and restored the relative position of the parts. When the membrane was relaxed, the pressure of the stapes was wanting, owing to the absence of resistance in the diseased membrane itself. Until we found some means of restoring this resistance, the deafness remained. Thus, by the loss of elasticity in this membrane we lost two important factors in perfect hearing: 1. This membrane, like the *membrana tympani*, when relaxed, failed to act as a conductor of sound by not responding to vibrations given it. 2. The proper relation between it and the stapes was destroyed, the necessary pressure and resistance being absent. We found, in the case of an atrophied drumhead, that hearing was frequently improved by inflating the middle ear, thus restoring the tension of the membrane by forcing it outward. One might suppose that such inflation would likewise restore the hearing when its loss was due to relaxation of the membrane of the *fenestra ovalis*; unfortunately, the same act which might restore its proper tension to the membrane at the same time forced it inward, thus separating the stapes from it. Though the membrane might be in a proper condition for receiving and transmitting sound-waves, the stapes, from the absence of any pressure applied by it to this membrane, would be unable to perform its duty—there would be more or less obstruction to the passage of sound at this point. Whatever, then, restored the hearing in these cases must not only renew the tension of the membrane, but maintain as well the normal relative position between it and the stapes. This, in the writer's opinion, could only be accomplished by some influence brought to bear upon the membrane and the stapes from outside the middle ear. If, now, we considered the effect of wave-impulses upon the membranes and the ossicles, we could understand how a loud and continuous noise (as the writer thought) might improve the hearing where the deafness was due to such pathological changes as had been described. The air set in motion by this noise struck upon the drumhead and upon the ossicles, and pushed them inward; this forced the air in the middle ear against the membrane of the *fenestra ovalis*, which, if relaxed, was made tense by this pressure. At the same time the relative position of the membrane and the stapes, as to pressure, etc., was also restored, and hearing was therefore improved for the time being. This noise, which would confuse a person with normal hearing, was absorbed, so to speak, in removing the cause of the deafness. In the case of a perforated drumhead the vibrating air acted directly upon the diseased membrane and stapes. Von Trötsch

mentioned the case of a magistrate who, being so afflicted, improved his hearing by pressing a bit of stick against his drum-head. Allen, also, in his "Aural Surgery," stated that the hearing power was increased in a patient who presented herself with marked destruction of the drum-head by pressing cotton against the ossicles. Another case had been noted in which a large perforation existed, and in which, both before and after the healing of the perforation, the hearing was improved by pressure. Although these three cases did not in themselves place this theory beyond dispute, they yet made it worthy of consideration, and might encourage us to further investigation.

Dr. S. J. JONES remarked that the condition was not always dependent on the same cause. In some cases pressing cotton on the stapes would increase the hearing power, a tuning-fork placed between the teeth might also be better heard with the affected ear, and often to place the hand on a piano would excite the affected ear to action more acute than that of the healthy one in the transmission of delicate sounds.

Chronic Cystitis with Hyperæsthesia of the Urethra; Perineal Cystotomy.—Dr. W. L. AXFORD related the case of a man, sixty-six years old, of a gouty diathesis, a gardener, who had been under treatment at intervals for the past eighteen months for chronic cystitis and hyperæsthesia of the urethra, and had also had attacks of nephralgia, which were relieved by hypodermic injections of a quarter of a grain of sulphate of morphine. In his last attack, however, this treatment afforded no relief, and rectal suppositories of opium and belladonna gave only partial relief. The urine was voided only by great effort, small quantities being passed every five minutes, and the bladder was full continually. This condition lasted for three days. Attempts at catheterization were attended with excruciating agony, which continued for four hours, and the catheter was introduced every six hours. Large doses of opium failed to relieve the pain produced by the extreme hyperæsthesia of the urethra, and, as a last resort, cystotomy was performed. It relieved the patient very much for the time, but he died in a few days. A drainage-tube that was introduced very soon became occluded with mucus and phosphates, the latter being withdrawn in masses as large as a pea. The cystitis was found to be exceedingly extensive, and the urine very fetid and ammoniacal. The man suffered also from an enlarged prostate. With reference to the operation, the speaker would do it again in a like case; it had been the means of relieving the patient from very acute pain, and had saved him at least a dozen catheterizations. The kidneys were found cirrhotic at the post-mortem, and the liver was in like condition.

Dr. C. T. PARKES approved of the treatment, and further stated that many cases of cystitis were best treated by median cystotomy.

LISTON H. MONTGOMERY, M. D., *Secretary.*

NEW HAVEN MEDICAL ASSOCIATION.

Meeting of June 16, 1884.

The President, Dr. F. E. BECKWITH, in the chair.

Fracture of the Spine in the Lumbar Region; Death from Tetanus.—Dr. H. FLEISCHNER presented a specimen with the following clinical history: The patient, a powerful, robust man, a roofer by occupation, seven years ago fell from a height of thirty feet, striking with his feet on some stones. He sustained a complete comminuted, but not compound, fracture of the tarsus, also fractures of the sternum, two ribs, and the left forearm, and an injury of the spine, the exact nature of which could not be determined at the time. His condition was dangerous, and early death was anticipated. There was paralysis

of the left lower extremity. For two or three days his bladder was emptied by the catheter, and his rectum by enemata. Then he commenced to improve, but recovery advanced very slowly. Hemiparaplegia, affecting the right lower extremity, persisted. His condition was a painless one for a year. Subsequently he suffered greatly from neuralgia, and became addicted to the habitual use of opium. He would inject hypodermically, during the paroxysms of pain, six, eight, or ten syringefuls of a saturated solution of morphine at once. His appetite was good and his general condition excellent. He was hopeful, and expected restoration to health. Last Wednesday evening he experienced difficulty in deglutition. Thursday morning he complained of pain in the back of the neck, and was able to swallow only on making considerable effort. It was clear that he was suffering from tetanus. In the afternoon there was marked emprosthotonus. Enemata of chloral were administered, but he did not sleep. Friday morning he had very violent spasms. He had had none before. At 6 A. M. his temperature was 103° F., pulse 110, respiration irregular; sometimes slow and sometimes fast. At 10 A. M., temperature 105°, pulse 140. He had been taking two grammes of chloral every two hours, and had taken four grammes during the morning. He was able to open his mouth slightly, and a little beef-tea was given which he swallowed more easily than before. His breathing at this time was harsh and stridulous. Suddenly there was relaxation of the spasm, and he died at once. Five minutes after death the temperature was 108°.

Dr. Fleischner presented the four upper lumbar vertebræ from this patient. The spinal curve in the specimen was in the wrong direction. The right inferior articular process of the second lumbar vertebra was displaced and enlarged. There was no intervertebral foramen between the third and fourth vertebræ on the right side. There was enlargement of the neural arch, with trabeculae of new osseous tissue inside the vertebral canal. The meninges were adenomatous and adherent to the vertebræ, and contained bony plates. The intervertebral cartilage between the second and third vertebræ on the left side was reduced to a mere trace; on the right side it was replaced by bony proliferation, and there was ankylosis of the adjacent vertebræ. There was no intervertebral opening on this side, which accounted for the paralysis. The cord ended lower down than usual, but above the seat of injury. There were bony deposits between the nerves and membranes lower down.

Renal Calculus.—Dr. M. C. WHITE presented a kidney, removed from a patient who died of Bright's disease, in the pelvis of which were two calculi, one of them as large as a hen's egg, the other somewhat smaller. There was also a tumor connected with one of the ovaries.

Heart and Aorta from a Patient who died during the Administration of Ether.—In presenting this specimen Dr. WHITE remarked that, in cases of death from the inhalation of ether, recent discussions in the Academy of Medicine of Paris had rendered especially interesting the inquiry as to the presence of air in the blood-vessels. Careful examination in this case failed to reveal the presence of any air in the heart, the great vessels of the trunk, or the vessels of the brain. The aorta and its branches, as well as the arteries in general, were atheromatous and calcified. The abdominal aorta contained a large calcareous plate. The ophthalmic artery was enlarged to twice its usual size, and was atheromatous. The heart was enormously hypertrophied, and weighed thirty-one ounces. The left ventricle was greatly thickened. The right was in a healthy condition. The mitral valve was ossified and contained calcareous plates about its base. The aortic semilunar valves were also ossified about their base, but they were not thickened so much as the mitral valve. The aortic orifice might have been well

closed by its valves, but the mitral probably could not. The right lung was in a normal condition. The left lung was oedematous.

Dr. BECKWITH, who was present when the patient, being about to undergo an operation for the relief of an inguinal tumor, died, stated that he died suddenly and unexpectedly. He had taken only a little ether, probably not more than two ounces. He became cyanotic and respiration ceased. The heart continued to beat for about eight minutes. Five minutes after the breathing stopped the pulse was 76, and strong. The tongue was pulled forward and artificial respiration employed, but without avail. He was unable to say whether the heart had been examined.

Aortic Aneurysm.—Dr. MAILHOUSE exhibited the heart and aorta of a man who died suddenly of hæmorrhage three or four weeks ago. He had suffered from rheumatism complicated by endocarditis last December, and had been continuously ill since. The heart was somewhat enlarged. The aortic valves were thick and nodular. The ascending aorta was dilated and showed evidences of endarteritis. The transverse aorta was dilated, forming a tubular aneurysm, and contained a clot. The thoracic aorta presented a sacculated aneurysm, nearly as large as the fist, which contained a clot, and from which there was an opening into the left bronchus. The specimen had been preserved in an undertaker's fluid, and was without odor.

Rhachitic Calvaria.—Dr. BECKWITH showed the calvaria of a child ten months old, which illustrated the condition of the anterior fontanelle in slight rhachitis. The specimen showed deficient ossification, not only at the circumference of the fontanelles, but also at circumscribed spots in the parietal and occipital bones.

The Therapeutic Use of the Digestive Ferments.—Dr. HERBERT E. SMITH read a paper on this subject. [See p. 9.]

Dr. C. A. LINDSEY, in opening the discussion, said that it had afforded him great gratification to listen to the paper by Dr. Smith, which treated the subject from a scientific standpoint, particularly in view of the fact that heretofore the chief literature of the subject had consisted of the advertisements of the manufacturing pharmacists, which were liberally circulated among the profession through the mail and by traveling agents. The practice of using these preparations had become so general that some establishments did a large business in manufacturing them exclusively. They were used, he believed, almost wholly without purpose and without good results. Personally, he had used them little, and the results had been unsatisfactory. He had derived advantage from the use of peptonized milk in a few cases in which the stomach could not retain anything else.

Dr. THACHER remarked that the changes which the sugars underwent in the body were of interest in connection with the pathology of diabetes. It had been suggested that sugar existed in the body in health chiefly in the form of maltose. Maltose was detected by the same qualitative tests as glucose, and rotated the plane of polarized light in the same direction. Quantitative tests, however, showed a difference. It had occurred to him to examine the urine of diabetic patients with reference to determining whether the sugar of the urine was maltose or glucose. In the cases of diabetes which had come under his notice during the last few years—some ten or twelve in number—he had found that the urine in each case contained glucose and not maltose. Perhaps it would eventually be found that the fundamental pathology of diabetes consisted in a change of the carbohydrates to some form of sugar not assimilable in the body. It was now, as Dr. Smith had said, generally admitted that the digestion of starch might go on during the early stage of stomach digestion. It should be borne in mind that the amount of action was not necessarily dependent on the amount of ferment in-

gested, for it was possible that, besides the direct action upon the food, there was also a stimulating action upon the gastric glands. Heidenhain's experiments seemed to prove this. He isolated a portion of the stomach of a dog, and placed digestible food in the other portion. He found that the amount of secretion in the isolated portion increased as the food in the other part became more fully digested. The secretion did not seem to depend merely on the presence of digested food, but of food which had been acted upon by the digestive secretions. His own belief was that the earlier the ferments were administered the better the result that would follow, if only they were not absorbed before secretion commenced. Early in the meal would seem to be the best time to give them. He was skeptical in regard to the safety of the passage of pepsin through the stomach. He did not regard it as certain that the products of protolytic digestion were all absorbed in the same state. The natural process might be that several proteids were taken up. If this was so, it was not desirable to carry artificial digestion too far, and particular care should be exercised to avoid the reduction of the products of this digestion to leucin and tyrosin.

Dr. SANFORD said that his experience bore out the suggestions of Dr. Smith. The watery extract of malt he had not found particularly useful. Maltine was appetizing and blood-enriching. It was of some aid to digestion, not in stomachal indigestion; but, when there was a deficiency in intestinal digestion, maltine did considerable good. He was quite certain that it was not always easy to get good pepsin. Perhaps this was the reason why pepsin had fallen into disrepute. Scheffer's saccharated pepsin had answered his expectations very well, because he did not use it indiscreetly. In cases of deficiency of gastric secretion he gave fifteen or twenty grains. His plan was to give an acidulated bitter tonic—for instance, Colombo with an aromatic and a drop of hydrochloric acid—before eating, and a large dose of pepsin after eating. If he was not mistaken, such treatment was very helpful. The good effect was not all due to the acid, nor, on the other hand, did stomachal indigestion do so well with pepsin alone. He was accustomed to use both and get good results. Small doses were insufficient. If the results were not satisfactory, it was sometimes necessary to repeat the dose at short intervals. Under such circumstances it was best administered in a solution with glycerin and an acid. Milk peptonized with Fairchild's extract of pancreas sometimes gave good results. It was not a good plan to give this preparation internally. He believed that generally the symptoms for the relief of which these preparations were given were due to a catarrh, and should be treated on the same principles as other catarrhs. The object of these remarks had been to speak well of pepsin if a pure article was used, and if it was given in good doses and in connection with an acid. Employed in this way, his experience had been that large doses never did harm and small doses seldom did good.

Dr. BARTLETT testified to the efficacy of pepsin given in good doses combined with other remedies in disturbances of the stomach and digestion.

Dr. LEIGHTON remarked that, when several active drugs were given in combination, it was not easy to distinguish the effect which was due to each one. He could recall fifteen recent cases in which he had prescribed, with good results, pepsin pure and simple, or mixed only with a little sugar and flavored. In an acid condition of the stomach, whether temporary or chronic, accompanied by eructations of gas, he had obtained positive, certain, and continuous benefit from two-grain doses of Fairchild's or Thayer's pepsin. Either gave perceptible results when taken unmixed after eating. Although neither was pure, each containing a large percentage of peptones, they were as pure

as could be obtained at present. His first experience in the use of remedies of this class had been with lacto-peptine, but he had left off using it, not because it was inert, but because it seemed unscientific. In his hands it had proved efficacious, doubtless because of the presence of a small quantity of pepsin.

The President stated that his experience in the use of pepsin coincided with that of Dr. Sanford. He believed that large doses never did harm, and that small doses seldom did good. He commenced with doses of a few grains, but quickly increased the dose to twenty grains of saccharated pepsin. For an adult the proper dose was from twenty to sixty grains. In full doses in infants it did some good. Given alone and in full doses it was possible to do a great deal with it.

In reply to an inquiry addressed to him, Dr. SMITH said that he had made no quantitative tests to determine the relative value of the different brands of pepsin. Fairchild's and Thayer's both gave a very fair result in the laboratory. Either was very efficient. He also remarked, in closing the discussion, that he had been gratified by listening to the clinical experience of the members, especially in regard to the use of extract of pancreas. He believed that it would be found difficult to hit upon the correct time to give it, and the requisite amount of alkali to give with it.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of May 28, 1884.

(Continued from vol. XXXI., page 732.)

Conclusion of Dr. Theophilus Parvin's Report of the Obstetric Department of the Philadelphia Hospital, for the Quarter ending April 30, 1884.—The occurrence of a chill at the onset of septicaemia is by no means a constant phenomenon. While Dr. Macdonald refers to a chill marking the advent of lymphangitis, Siredey regards it as always present in phlebitis, usual but not invariable in lymphangitis; it is multiple in the former, single in the latter. The cases observed at the hospital show that a chill was not constant in septicaemia, even in a fatal form of the disease. While we may in some cases, by the great variations in temperature, be able to diagnose between septicaemic phlebitis and lymphangitis, there are decided oscillations in temperature observed in the latter, though much less

Bertha Lambert, aged twenty-five; puerperal septicaemia:

* Pulse before chill, temperature afterward.

+ Child died of pneumonia.

than in the former; and, besides, some cases present the combined forms, lymphatics and veins alike affected. There is herewith presented the temperature chart of a patient who suffered with what I at the time believed to be lymphatic septicaemia, and yet the reading of the chart might justify the conclusion that the disease was phlebitic, though early in its manifestation.

Looking at it, one sees that the temperature was normal until the morning of the third day, when the first chill occurred; at that time it rose to 103°; the next day a chill in the evening, and the mercury marked 106°, but fell the next morning to 100°; the next most marked difference was observed on the ninth and tenth days; the evening of the former it was 101.8°, the next morning 98.6°. I show a second temperature chart of

Kate Fleming, aged twenty-two; puerperal septicaemia:

DATE.	PULSE.		DAY OF DISEASE.	TEMPERATURE.

3	80	..	24	97.0

a patient whose temperature was under 100° until the fourth day; was 104.4° the seventh day, dropping to 99.6° the eighth day; reached 105° on the eleventh day, the twelfth only 101.4°; and who had in the course of her illness at least two chills.

The cases of septicaemia were too few, and the discrimination between lymphangitis and phlebitis not always made, to permit me to give a positive opinion; nevertheless, it seems to me probable that in lymphangitis the oscillations of temperature are always such that the thermometer marks a higher degree in the evening, while in phlebitis the highest temperature occurs quite as often in the morning as in the evening.

Returning to the subject of normal temperature in puerperality, it will be seen from the chart presented that the temperature of the third was no higher than that of the first or of the second day. In looking at a temperature chart given by Dr. Macdonald (Edinburgh "Obstetrical Transactions," vol. vi), taken as the result of observing the temperatures of thirty women, I find the highest temperatures the third, fourth, and seventh days; the thermometer registered 99.5° the third day, and 99.2° the fourth and seventh days.

Tarnier remarks that momentary elevations of temperature do not generally involve an unfavorable prognosis; but, when they are progressive and continuous, especially when the thermometer placed in the axilla goes above 100.4°, some complication is to be feared.

One of the subjects delivered at the hospital had a slightly subnormal temperature. She was a girl, eighteen years of age, who, three hours after a normal labor, had a temperature of 99°; this fell so that on the third day it was only 98°, and so

continued for a week. During a part of this time her pulse was 56, and even only 48.

The presence of albumin in the urine of the pregnant woman has often, even generally, engaged the attention of obstetricians; but comparatively little concern is usually shown as to its presence during labor, or in the puerperal state. Possibly it may be quite as important to examine the urine of the lying-in as of the pregnant woman, especially if she has had even slight septicæmia.

But, first, how frequent is albuminuria in pregnancy? In seventy-two pregnant women, albuminuria was found in five. It will be observed that this proportion is very much less than that given by Charpentier,* quoting Dumas, who, combining the statistics of several observers, makes the proportion one to five or six. It seems to me, both from hospital statistics and from observations in private practice, this proportion exaggerates the frequency of the accident.

By the albuminuria of labor is understood not only the disorder as occurring during labor, but also that of the two or three days immediately preceding. This is very much more frequent than the albuminuria of pregnancy, but the cases examined with reference to this point were too few to determine the proportion.

Seven of the seventy-two women had albuminuria after labor; I think the number was much greater, but some of the women suffering with septicæmia did not have the urine examined until after convalescence, and the results of examinations made in others were not properly kept, or at least were not placed in my hands.

In three of the seven mentioned the albuminuria was slight and transient. In four women convalescing from septicæmia, the urine was found to be albuminous one month after delivery. Two had pus, blood, and hyaline casts in the urine; in a third, no pus, but blood and casts were present in the urine; as to the urine of the fourth, the microscopic appearances were not noted. In regard to two of these patients, I know that the catheter was first used after their being brought from the "fever" to the "convalescent ward," and therefore the explanation which Ols-hausen has suggested of the renal disorder fails in these cases; catheterism had nothing to do with its causation. In explanation of these cases, it is probably better to accept the teaching of Siredey, who regards puerperal nephritis as a constant complication of uterine lymphangitis or phlebitis.

Women may apparently, but not really, recover after pregnancy and labor; especially if there has been septicæmia is there a liability of renal disorder becoming chronic, and it is only by actual examination of the urine that the integrity of the kidneys can be determined.

Mauriceau compares the pregnant woman just before labor to a ship that has been nine months tossing upon a rough sea, and urges the importance of not letting the ship sink as she enters the port of childbed. It is not less the duty of the obstetrician to know that the ship has not suffered such damage on the ocean or in the port that she is unfit, without important repairs, to run the risk of another voyage.

Sugar in the urine of pregnant and of nursing women was first shown to occur by Blot in 1856. Differences of opinion hold as to the constancy of its presence in the conditions stated, as to its source, and as to its character. Macdonald found it in each of thirty-five cases whose urine was examined, and therefore regards it as present in all cases at some time or other of the puerperium. But neither Kleinwächter nor Spiegelberg refers to it as always present. In the examinations made daily of the urine of fifty women at the hospital (these examinations began a few days before and continued seven days after labor),

four women had sugar in the urine before labor, and six after labor, one of the six being also one of the four. In this woman the sugar was constantly and largely present up to eight weeks after delivery; she had remarkably well-developed mammary glands, and a most abundant secretion of milk. In this case Blot's suggested test for a good nurse—to wit, the quantity of sugar contained in the urine—would have proved true, so far as abundance of milk was concerned.

It has been shown that abrupt suppression of nursing causes the appearance of sugar in the urine; thus it is commonly observed in mammary abscess.

The fact that removal of the mammary glands in an inferior animal recently delivered causes disappearance of sugar from the urine, proves that it is incorrect to call the cases where sugar is found in the urine in pregnancy or childbed cases of glycosuria, but rather of lactosuria, unless we attach only the literal meaning to the first word in the compound glycosuria. Spiegelberg refers to the condition as an absorption diabetes; and this seems the opinion of most authorities. Tarnier, however, regards as very plausible the hypothesis that the sugar eliminated by the kidneys was sugar made very probably by the liver in view of the lacteal secretion, and which was not utilized in consequence of the momentary suppression of this function; further, he thinks new researches necessary, in addition to those of Hofmeister and others, to determine the question as to whether this sugar is glucose or lactose.

Whenever there is an exact correspondence between the milk supply and the demand, the former not being in excess of the latter, it is probable sugar will not be found in the urine; I think, therefore, that the experience of Macdonald—showing saccharine urine in all cases of lying-in women—is not the law.

An interesting case of secondary puerperal hæmorrhage occurred—interesting as to its ætiology, and instructive as to the means by which it was finally arrested.

The following is the history as given by Dr. Voorhees, the interne who had charge of the patient:

A. A., German, single, primipara; varicose condition of veins of lower limbs, this condition disappearing after labor. Labor at full term, March 5, 1884, lasting a little over twelve hours. Her condition was perfectly satisfactory up to the evening of the eleventh day after confinement; on that day she was transferred to the convalescent ward, and then saw the out-door agent as to keeping the father of her child in prison for refusing support. She was greatly distressed by this interview, and at 4.30 the next morning hæmorrhage began. Digital examination showed that the blood came from the uterus; the os was high up, flabby, and full of clots; the uterus was as large as if delivery had just occurred, and was soft and relaxed. Ergot was given; the child applied to the breast; the uterus was emptied of its clots, and friction used to stimulate contraction, but the bleeding still continued. Ice was then used to the abdomen and in the vagina; the bleeding was not stopped. Hot water was then freely thrown into the uterus, and the result was prompt and satisfactory. The patient made a good recovery. Although the uterine discharges were carefully examined, at no time was there any organized material found, nothing in the least indicating that this hæmorrhage was caused, for example, by the retention of a placental fragment.

Those who have read Dr. Fordyce Barker's admirable lectures upon puerperal diseases will remember the graphic description of a case of secondary hæmorrhage the second day of lying-in, due to an emotional cause, and in what perilous condition the poor woman was for some days. So, too, in the hospital case we have an example of hæmorrhage from a psychical cause. Believe or doubt as we may, say what we will, there are at times in medical practice just such sudden, startling, and strong proclamations of something more than flesh and blood in this human nature, telling us that the coarse material may be

* "Traité des accouchements."

prostrated through the finer spiritual, the psychical assert its power over the physical.

Further, as to this case, the great value of hot-water injections for the arrest of uterine hemorrhage never had a more striking illustration.

The final subject presented to you is that of uterine rupture. In reflecting upon the history of my three months' service, no event occurred in my duties to these unfortunate women—women often worthy of the profoundest pity as the victims of misfortune and of man's perfidy—which causes me greater sorrow in silence or in recital than a case where the uterus was ruptured in consequence of a shoulder presentation—a case which ended in death the eighth day after delivery. Yet I should fail in duty to my profession, that has been so good, so generous to me, if I did not make the case fully known. The patient was a well-formed, healthy multipara; she had been in labor nearly twelve hours when I first saw her, the left shoulder presenting. Ether was immediately given until she was thoroughly under its anæsthetic effect; and then, without violence, nay, with great ease, I passed two fingers behind the right knee, brought the foot down, and turning and delivery were effected in a few minutes; the placenta followed almost immediately; the child, quite a large one, was dead. The patient came out from the anæsthesia satisfactorily; her pulse was good; there was no complaint, no shock, no great hemorrhage. Yet that woman had a ruptured womb, the tear beginning at the os uteri on the right side, involving the cervix and the lower part of the body of the uterus, this condition being made known by the post mortem. If it be thought I ought to have known this accident at the time of delivery, I can only say that like ignorance happened to Dubois, to Hervieux, to Tarnier, and others—the first revelation of the uterine rent being made at the post mortem; these silent tears of the womb are, as Hervieux has suggested, probably more frequent than generally thought. No, my self-reproach is not in this, but in not having made myself, or by another, an examination during pregnancy, so that the abnormal presentation could have been corrected, if not then, at least early in labor. But let this pass. The great practical lesson to be drawn from the accident is not only the importance of an early rectification of a mal-presentation, but also an appreciation of the danger of rupture of the uterus, and how this accident occurs. The drawing now shown gives the position occupied by the child, and also and especially gives the change in form and thickness of the two cavities of the uterus, which, as so admirably described by Bandl, are formed when nature is unable to overcome the obstacle to labor found in such case. The one cavity is formed by the body of the uterus, and its walls become thicker and stronger; the other, by the cervix, and its walls grow thinner—become, indeed, so attenuated and weak that a very slight additional strain causes a tear at some point; that strain may come from a uterine contraction, or solely from the introduction of the finger; and thus peril from action, peril from delay, must be before the obstetrician's mind when called to a case of neglected shoulder presentation.

Of course, had I seen this patient an hour or two earlier, the event might have been different. The pressure of the presenting part had been so severe that a slough of the vesicovaginal wall occurred, and the patient, had she recovered, would have required an operation for the resulting urinary fistula; I have thought that possibly the uterine rent was in part the result of a slough also; but, be this as it may, there was not the slightest indication given at the post-mortem that any hemorrhage into the abdominal cavity had taken place.

One other topic I had designed presenting—the prophylactic treatment of puerperal septicæmia—but my paper has already occupied enough, possibly too much, of your time.

NEW YORK CLINICAL SOCIETY.

Meeting of February 22, 1884.

Dr. J. E. WINTERS, Chairman for the evening.

The Significance of Glycosuria in connection with Disease of the Brain and Cervical Cord, and with Dementia Paralytica.—Dr. A. McLANE HAMILTON read a paper with this title. [See p. 1.] Under the rules, the discussion was postponed until the next meeting.

Empyema (?) cured by Absorption.—The CHAIRMAN showed a child, three years old, who, when about twenty months old, began to suffer from pleural effusion, which lasted for nine months, six weeks having elapsed before he saw the case. The effusion on the left side was so great as to displace the heart an inch and three quarters to the right of the sternum. Under a tonic course of treatment, absorption progressed so far that the heart's impulse was to be felt in the median line, when an attack of measles took place, and was followed by a fresh accumulation. Seven weeks later, marked hectic fever came on, with night-sweats, and the child became very much emaciated and extremely anæmic, with clubbing of the fingers. Physical signs of disease in the other side of the chest appeared, and there was considerable stupor at times. After existing for nearly two months, these symptoms gradually subsided, and the child began to improve quite rapidly—absorption took place, the signs in the opposite lung cleared up, and the child had been practically well since June last. He was now well nourished, his appetite was excellent, there was no apparent retraction of the left side of the chest, and none could be made out by measurement. There was, however, a little dullness over the base of the left lung, and occasional friction-sounds were heard, but the heart was no longer displaced. Besides the tonic medication mentioned, frictions with a stimulating liniment had been used three times a day, for twenty minutes at a time. An exploring-needle had never been introduced, but the Chairman thought there could be very little doubt of the purulent nature of the effusion, because it continued so long, because of the intercurrent measles, and because of the hectic and the clubbing of the fingers, although the latter condition might have come on in the course of a serous effusion. As to the persistence of the physical signs, he had often seen it in cases of bronchitis long after the symptoms had disappeared.

Dr. ROBERT ABBE could not but feel that the Chairman's case lacked the proof of the hypodermic syringeful of pus, although it was probably one of empyema.

In reply to questions, the CHAIRMAN said that the family history was good, and that there had been no diarrhœa during the illness.

Dr. L. E. HOIT asked the Chairman if he had used cod-liver oil by inunction in this or in like cases.

The CHAIRMAN replied that the patient had taken the oil well by the mouth throughout the illness. He had given up its use by inunction, as the stomach was almost invariably affected by the odor, but he had seen good results from inunctions with equal parts of olive-oil and alcohol.

Diffuse Suppuration of the Pelvis and Thigh.—Dr. L. B. BANGS related the following case, and asked for a diagnosis: A man, thirty years old, was seen in his service in Charity Hospital. The case had been brought to his notice as one of bubo and intermittent fever. In January the right thigh became flexed and rotated inward. On examination, he found slight discoloration of the skin in the groin, a diffuse induration extending along Poupart's ligament toward the hip, and an obscure sense of deep fluctuation. After several days of poulticing, two small openings were seen in the groin, which were enlarged, when a

considerable quantity of very fetid pus was discharged, welling up from the deeper structures. The man gave a history of some pain in the back, not severe, and of a subsequent gonorrhœa with suppurating bubo, which latter had healed. There was some tenderness over the spine at the first lumbar vertebra. Nothing was found on examination of the ilio-costal region, the ilium, or the hip joint. The three sinuses were now probed, and were found to lead deeply to the inner side and anterior aspect of the thigh. One opened just outside the femoral artery. The general condition of the patient continued to depreciate, he had considerable fever, and four days ago he was etherized and the parts were laid open freely. A large cavity of pus was found on the inner side of the thigh, which communicated with the pelvis beneath Poupart's ligament. This was large enough to admit the finger. A probe was passed into it to the depth of two inches in the direction of the course of the psoas muscle, but would go no farther. No dead bone was found. Beneath the fascia lata several smaller cavities were found, discharging the same foul pus. Straining efforts by the patient forced out pus in considerable quantities from the pelvic opening. Counter-openings were made on the outer side of the thigh and drainage-tubes were inserted. A drainage-tube was passed into the pelvic opening as far as it would go, and it was ordered not to be syringed out. The temperature fell the next day to 100° F., and had since been normal. There had been very little discharge from the pelvic sinus. The patient expressed himself as feeling better than for a long time. Pott's disease, disease of the bones of the pelvis, and perinephritic abscess had all been thought of, but sufficient symptoms were not present to warrant any of these diagnoses.

Dr. ABBE suggested perityphlitis as a possibility, but thought, on the whole, that caries of the spine was the most plausible diagnosis. He had himself treated a large psoas abscess by repeated aspirations, in which no deformity of the spine existed and no evidence of vertebral disease could be discovered for a long time. Yet, at the autopsy, four vertebrae in the dorso-lumbar region were found carious.

Webbed Fingers.—Dr. ABBE presented a cast of a child's hand, illustrating a congenital deformity. There was webbing of the fingers, most marked at their extremities. He thought the case amenable to treatment by operation. There was also talipes varus of one foot, with some deformity of the toes.

Fibrous Polypi of the Rectum.—Dr. CHARLES B. KELSEY related the case of a man, thirty-five years old, who had been supposed to be suffering from piles for fifteen years. An examination showed two hard, whitish tumors projecting from the anus, one as large as a hen's egg, and the other about half as large, attached to opposite sides of the rectum, just within the internal sphincter. The pain on defecation was exceedingly severe, and there was profuse bleeding. The patient reduced the tumors himself on each occasion, but only with a good deal of suffering. Each tumor had a firm, good-sized pedicle. Both were removed with the clamp and cautery, together with a third one, attached posteriorly, which was smaller. Microscopic examination had shown the growths to be fibro-sarcomata. The patient recovered rapidly, and the relief was perfect.

Cancer of the Rectum; Excision.—Dr. KELSEY also related a case of this sort, which will be published hereafter. He raised the question whether the patient's chances would have been improved if the peritoneal wound had been sewn up. The statistics of between one hundred and fifty and two hundred cases showed only two recoveries after the peritonæum had been opened. He was opposed to any operation for the removal of cancer which involved opening the peritonæum.

Dr. BANGS did not see how, in the case related, sewing up the peritonæum would have affected the result.

Dr. ABBE thought the hot water and the iron solution had had something to do with producing shock, by their forcible entrance into the peritoneal cavity. Hence it seemed to him that it would have been better to sew up the peritonæum.

Dr. C. C. LEE, present by invitation, related two cases of accidental rupture of the rectum from dilatation of the bowel for stricture, in which recovery had taken place. In one there were no untoward symptoms; in the other there was great shock from peritoneal hemorrhage.

Dr. KELSEY expressed himself in favor of dividing strictures of the rectum with Paquelin's cautery, instead of performing lumbar colotomy.

RHODE ISLAND MEDICAL SOCIETY.

Seventy-third Annual Meeting, held in Providence, Thursday, June 19, 1884.

The President, Dr. JOB KENTON, in the chair.

The Secretary's Annual Report.—The meeting having been called to order, the secretary, Dr. GEORGE D. HERSEY, read the minutes of the previous meeting, after which he read his annual report, by which it appeared that four meetings had been held during the past year—three in Providence and one in Newport. Four fellows had died during the year: Dr. T. W. Perry, Dr. Otis Bullock, Dr. Uriah H. Holbrook, and Dr. James Millar; two fellows had removed from the State, and withdrawn from the Society; nine new fellows had been admitted. The present number of active members was one hundred and eighty-seven.

The Fiske Fund Prize.—Dr. C. W. PARSONS read the report of the trustees of the fund. They had awarded a prize of \$300 for the best essay on "The Origin and Progress of the Malarial Fever now Prevalent in New England" to Dr. C. V. Chapin, the Superintendent of Health of the City of Providence. The prize for an essay on the other subject proposed had not been awarded. The following subjects were proposed for the year 1885: "Original Investigations in Household Hygiene," "The Present State of the Germ Theory of Disease," "Physiological and Pathological Effects of the Use of Tobacco," "Migraine, its Nature and Treatment"—the prize for the best essay to be \$200.

Reports of the Board of Censors were read by Dr. J. W. C. ELY. They recommended the following-named gentlemen for membership: Dr. HENRY S. SWAN, of Bristol; Dr. WILLIAM A. TREMAIN, of the Rhode Island Hospital; Dr. BYRON J. LILLIBRIDGE, of Providence; Dr. SANFORD S. BURTON, of Providence; Dr. BENJAMIN R. SYMONDS, of Providence; and Dr. ABRAHAM L. FALCON, of Central Falls. These gentlemen were afterward elected. Dr. LLOYD MORTON was recommended for anniversary chairman for 1885.

The Medical Examiners' Bill.—Dr. LLOYD MORTON reported, in behalf of the committee, that the bill had been passed by the General Assembly, in a modified form, to take effect on the 1st of July, 1884.

Officers for the Ensuing Year were then elected as follows: *President*, Dr. OLIVER C. WIGGIN; *First Vice-President*, Dr. HORACE G. MILLER; *Second Vice-President*, Dr. JOHN W. SAWYER; *Recording Secretary*, Dr. GEORGE D. HERSEY; *Corresponding Secretary*, Dr. EDWARD M. HARRIS; *Treasurer*, Dr. CHARLES H. LEONARD; *Censors*, Dr. ARIEL BALLOU, Dr. J. H. ELDRIDGE, Dr. J. W. C. ELY, Dr. G. P. BAKER, Dr. S. S. KEENE, Dr. BENJAMIN GREENE, Dr. E. T. CASWELL, and Dr. G. KINGMAN.

The Annual Address, on "Theism Viewed from the Physician's Standpoint," was then delivered by Dr. GEORGE I. CHACE.

The Anniversary Dinner was held at the Narragansett Hotel after the adjournment, Dr. J. W. C. ELY presiding.

Miscellany.

THERAPEUTICAL NOTES.

The Pharmaceutics of Nitroglycerin.—A somewhat amusing account is given in a recent issue of the "Gazette hebdomadaire de médecine et de chirurgie" of the difficulties encountered by a physician in attempts to obtain a preparation of nitroglycerin for medicinal use. One after another, the various apothecaries and manufacturing druggists to whom he applied confessed their inability to meet his demand, chiefly on account of the danger they supposed to lie in handling the substance. The doctor plaintively recounts these facts in a letter addressed to the editor of the "Gazette," and a member of the editorial staff, M. Vigier, makes the letter a text for a brief exposition of the pharmaceutics of the drug.

Although nitroglycerin itself is very explosive, there is no danger in handling or transporting the pharmaceutical solution, and the one-to-one-thousand solution may even be intrusted to patients. The nitroglycerin of commerce is made as follows: On the one hand, glycerin is mixed with three times its weight of concentrated sulphuric acid, and, on the other hand, *fuming* nitric acid is mixed with its own weight of concentrated sulphuric acid. The two mixtures are allowed to cool, then the one is added to the other, and the mass is left to itself for a few hours, when the nitroglycerin will be found to have fallen to the bottom of the vessel, and nothing remains but to wash it. The reaction between the monohydrated nitric acid and the glycerin is the following:

Nitroglycerin is a very stable and a very manageable substance, requiring to be guarded only against the effects of heat and of blows. It is almost insoluble in water, and is soluble only in strong alcohol. A one-per-cent. solution answers all the requirements of medicine. Dynamite, which is less dangerous to handle than nitroglycerin, is a mixture of aluminous earth with about two thirds its weight of the explosive; it burns without exploding, and detonates only under the action of fulminate of mercury.

The medicinal solution recommended by M. Vigier consists of one part of nitroglycerin and 999 parts, by weight, of ninety-per-cent. alcohol. Of this mixture five drops may be taken three times a day, in a little water, and the dose may be increased carefully to ten drops. The greatest caution is necessary in increasing the dose, not because the drug is poisonous in any ordinary doses, but because it is apt to give rise to most excruciating headache. Huchard's solution, recommended by that author for the treatment of angina pectoris, consists of thirty drops of a one-per-cent. solution of nitroglycerin in three hundred grammes (about ten ounces) of distilled water. Of this solution three dessertspoonfuls are to be taken daily at first, and then three spoonfuls.

The one-per-cent. solution is also employed hypodermically, but its administration by the mouth is to be preferred. Nitroglycerin is also called trinitrine, trinitrate of glyceryl, and glonoin.

The Tar-and-Turpentine Treatment of Diphtheria.—A correspondent of the same journal gives an account of his failure with this treatment in every one of four cases in which he tried it. The children all died, although the details of the method were carried out with the utmost exactness. The parents would not allow tracheotomy to be performed. The writer does not even think that the treatment gave any noteworthy palliation. While declining to pronounce judgment on this method in advance of further data, the editor of the "Gazette" adds that what he knows of it, so far, is not in its favor.

The so-called "Ozonizing Water."—At a recent meeting of the Paris *Société de thérapeutique* ("Gazette hebdomadaire de médecine et de chirurgie") M. Tanret stated that the name given by M. Boursier to his "ozonizing water" (*eau ozonisante*) was absolutely incorrect. We could not apply the term hydrate of terpene to an oxygenated watery solution of terpene, the hydrate of terpene being, as had been known for a long time, the definite, crystallized terpin formed by the combination of water with the terpene, or terebenthene, contained in oil of turpentine. M. Campardon had used the *eau ozonisante* in a case of diphtheria, but, although it had seemed to aid somewhat in the detachment

of the false membranes, he could not speak positively on that point, for the disease was already declining when the use of the remedy was begun. The solution did not seem to be a definite new compound; its odor was very much like that of the solution of *baume du commandeur* (an alcoholic solution of Peru balsam, benzoin, and a number of aromatics) which one of his patients had devised as a disinfectant. M. Tanret alluded to the fact that Berthelot's experiments had shown conclusively that oil of turpentine, although it absorbed oxygen, retained it in a very unstable combination, and then parted with it with great facility, so that it might play the part of an oxidizing body, did not really produce ozone under the conditions in question.

The Action of Quinine on the Cerebral Circulation.—Curci ("Sperimentale"; "Bull. gén. de thérap.") maintains that quinine has rather a tendency to produce anemia than hyperemia of the brain, and that it checks the effect of morphine in producing hyperemia. Therefore, he thinks, it is not contraindicated in the subjects of cerebral hyperemia, but, on the contrary, its beneficial action in sunstroke is probably due to its tendency to reduce the hyperemia.

The Kola Nut as an Astringent and Tonic.—M. Dujardin-Beaumetz showed a specimen of the fruit of the *Sterculia kola*, a tree indigenous to Central Africa, at a recent meeting of the Paris *Société de thérapeutique* ("Progr. méd."), and remarked that analysis showed that it contained a large amount of caffeine, tannic acid, and a little theobromine. Naval surgeons had employed it with success in the chronic diarrheas of hot climates, and its use was likewise indicated in cardiac affections and in the cachexia. He himself had seen good effects from it in these cases, given either in the form of an infusion of the roasted nut, as an elixir, or in the shape of chocolate. In all these cases it acted as a tonic and astringent.

Antipyrine, a New Antipyretic Alkaloid.—In the "Zeitschrift für klinische Medizin" (quoted in the "Centralbl. f. d. ges. Ther."), Filehne sets forth the medicinal properties of a new artificial alkaloid termed antipyrine, but does not give the method of its preparation or its chemical constitution. It seems to act very much like kairine, but to be free from some of the objectionable properties of the latter drug. The dose for an adult is thirty grains, to be repeated in an hour, and, at the end of another hour, the same amount or one half the quantity may be given again. For children the dose is from half to two thirds the dose for adults, and some reduction is advisable in the case of adults who are debilitated by chronic disease. At the time the article was written the preparation was not in the market.

The Late Dr. John G. Adams.—At a stated meeting of the Council of the New York Academy of Medicine, held June 24, 1884, the following preamble and resolutions were unanimously adopted:

Whereas, The Council of the New York Academy of Medicine has heard with profound regret of the recent death of their associate, Dr. John G. Adams, an original fellow, and at the time of his decease Corresponding Secretary of the Academy,

Resolved, That the Council desire to put on record their warm appreciation of his fidelity to his convictions, his genial friendship, his ripe culture, his courtesy, his liberal, earnest, and persistent interest in the Academy, and of his gentlemanly and Christian character.

Resolved, That a copy of the above preamble and resolution be entered on the minutes, be published in the medical journals of the city, and sent to his relatives.

G. M. SMITH, M. D.,)
H. T. HANES, M. D.,) *Committee.*

The Illinois State Board of Health is now engaged in revising the Register of Physicians, preparatory to publication. Any changes or corrections should be promptly sent to the secretary. Lists of the officers of the medical societies in the State are also requested.

Lactopeptine is a remedy which is constantly gaining in favor with the profession. Our own experience with it has been most satisfactory. In the summer complaint of children we have used it with excellent results. Indeed, we have found it very valuable as a preventive of this affection. We frequently order it, with this object in view, and we believe that our expectations have been realized.—*Canada Medical Record.*

GUNSHOT WOUNDS OF THE LARYNX, WITH THE REPORT OF A CASE IN WHICH THE VOCAL BANDS WERE INVOLVED.*

By WILLIAM H. DALY, M. D.,

PITTSBURGH, PA.

THE literature of gunshot wounds of the larynx has not, so far as I am aware, been collated, excepting the cases compiled in the Medical and Surgical History † of the late War of the Rebellion.

These are peculiar as a class, from the fact that the missiles producing nearly all of them were of a large caliber. Of the thirty cases there tabulated as involving the neck and larynx, ten were fatal, and the termination of ten more was unknown; eight patients were discharged, and two returned to duty.

Not having sufficient time in which to collate all the cases that might be more or less accessible, I have thought it not out of place to append to this report such a bibliographical list as I could obtain, which may aid others alike interested in this study in doing a piece of work that ought to be of signal and lasting interest to the throat surgeon as well as the general practitioner.

This can only be done by a systematic and extensive inquiry from the general profession, gathering cases here and there from the experience of private practice, and formulating them.

Such a work would at once be not only valuable, but highly interesting; and it is eminently fitting that this should be engaged in, at no distant day, by the learned body of throat surgeons represented by our Association (this assemblage).

The compilation of the cases of gunshot wounds of the neck involving the larynx and other portions of the air-passages, as well as the upper alimentary tract, found in the "Medical and Surgical History of the War," is a piece of work quite in keeping with the high character of all the other carefully digested records of work done by the army surgeons of the late war; and it is a pleasure to note among the contributors to this department the name of our esteemed colleague, Dr. S. W. Langmaid.

But, for civil surgeons, there should be a collation of cases from private practice covering the entire United States.

The missiles producing wounds in other than army life are of smaller caliber, and it is rather difficult to make a comparative deduction from the army records that would be found useful to us as civil surgeons.

Of some of the consequences of wounds of the larynx, aphonia is, as a matter of course, the most common; also exfoliation of cartilage, persistent fistula, and permanent

distortion of the vocal apparatus. Six of the ten cases detailed in the war record referred to were followed by chronic cough and complete loss of voice, and similar results are described as occurring among those so wounded on the Confederate side.

Of the general report of 4,895 cases of gunshot wound of the neck in the late war, there was a death-rate of fifteen per centum.

But it must be understood that the figures were taken from the casualty lists and regimental field reports as well as returns from base or general hospitals, and thus the excessive mortality is explained, and many cases are included of grave injuries that never came under treatment; and few indeed that probably came under the treatment that the more modern surgery of the throat would afford, since the advances in this department have been greater subsequent than previous to or during the war.

On reference to some of our text-books we find but meager information on the subject. "The danger of such lesions penetrating the larynx," says Gross, "will be particularly great if, as sometimes happens, the opening extends to the vocal cords, as œdema of the glottis will then be almost sure to arise and occasion fatal suffocation.*

Cohen † speaks of the liability, in gunshot wounds, to serious contusion or laceration of the important nerves on the side affected, and ensuing paralysis or spasm of the muscles of the glottis, interfering with respiration.

The case which is here presented to you for your examination is that of a young man, aged eighteen, H. C. D., by occupation a student, who received, accidentally, a gunshot wound in the neck, from a .32 caliber pistol in the hands of a school-mate, on the night of October 29, 1883, at a boarding-school in the State of Delaware.

The ball struck the neck a little anterior to and below the angle of the jaw on the right side, the pistol being held about five feet from the parts, the bullet taking a transversely downward course through the two walls of the larynx, and finally lodging upon the subclavian artery at the opposite side from the point of entrance.

The symptoms arising immediately after the injury were: stinging or burning at the point of entrance of the ball, a sense of fullness in the throat, and a desire to clear it, the latter act being followed by the expectoration of fresh blood; hoarseness at first, which constantly increased until, within a few hours, there was complete aphonia.

This, in brief, was the history of the case up to the time I was called, November 5, 1883, seven days after the reception of the wound, to see him at his school, where he was attended by Dr. Chandler, of Brandywine, and Dr. Draper, of Wilmington, as consultant. With the former I made an examination of the patient. Externally, over the region of the neck, throat, and upper part of the chest, there was swelling with discoloration from extravasated blood; there was also emphysematous crepitation in the cellular tissue of the neck and chest.

There was a look of anxious alarm about the face; respiration nearly normal, but labored about the region of the larynx. Placing the patient carefully in a sitting position, a laryngoscopic examination was attempted, which revealed œdema of the glottis, with evidences of traumatic discoloration of such a

† Cohen, "Diseases of the Throat and Nasal Passages," p. 603.

character as to utterly destroy all the anatomical landmarks of the parts; a superficial examination was made for the ball, and a point found on the opposite side, six inches from the point of entrance immediately behind the left clavicle, that was exceedingly tender to the touch. While the ball could not be felt here by mere palpation, I strongly suspected that it was in this immediate locality, and, fearing further delay in its removal might result in secondary hemorrhage, urged an attempt to discover its whereabouts by careful dissection.

This was acceded to by the attending physician and the father of the boy. The patient was prevailed upon to undergo the ordeal without an anesthetic, fearing its use might bring on emesis and precipitate hemorrhage, which it was desirable to avoid. A careful dissection at the point shown by this cicatrix was carried down deeply behind the clavicle, through tissues much swollen and ecchymosed, and predisposed to bleed.

This was done by drawing down the skin and superficial fascia and making the first incision upon the clavicle, then with the handle of the scalpel and a grooved director tearing my way down, carefully exploring as I went.

I was finally rewarded by being able to feel what I supposed to be the missile slipping away into its track at every effort to touch it; but, after further careful dissection, the ball was discovered and laid bare, immediately upon the subclavian artery, where its elevation with each pulsation of the blood-vessel was noted.

The ball was removed, and the wound made for the purpose healed kindly; twenty-one days later the boy had progressed so favorably as to make it desirable to take him to his home near Pittsburgh, stopping *en route* in Philadelphia, November 26, 1883, to enable us to obtain an examination and counsel in the case from our friend Dr. Cohen.

This was done at Dr. Cohen's office, as thoroughly as the case would admit of, the traumatic changes in the larynx being of such a character as to make it impossible to discover the anatomical relations in any degree whatever.

There was complete aphonia, and the caliber of the glottis was probably less than one fourth of its normal size. Dr. Cohen was not of the opinion that the ball had penetrated the laryngeal walls, and further thought that the fixation of the left arytenoid in the position of farthest separation from its fellow was due to inflammatory changes which had taken place after the reception of the wound, and not to lesions caused immediately by the destructive force of the ball.

This was an opinion which he qualified by remarking our palpable inability at this time to make a satisfactory, or, in fact, any examination whatever of the interior of the larynx; stating, very properly, that nothing short of a daily study and observation of the case would lead to a comprehension of the lesion, and that the probable destructive changes which had been wrought rendered a favorable prognosis for recovery of vocal powers almost impossible.

In this opinion I fully concurred. However, three weeks after this consultation, when the tamefaction of the internal parts had subsided sufficiently to bring more of the interior of the larynx into view, I discovered a ragged lesion of the right vocal band near its middle portion, which nearly severed it, and which distinctly marked the entrance of the missile into the larynx, and, at the opposite side, a spot which, upon careful study and observation, plainly showed the point of exit of the ball from the larynx to be just at the lower portion of the ventricle of Morgagni, or immediately above the true vocal band, splitting the band, as it were, at its upper border. The first spot is now marked by a serrated cicatrix in the true vocal cord, and the opposite side is marked by more extensive post-lesional inflammatory changes, still apparent in the image of the larynx.

At this time I thought it expedient to resort to the use of the mild interrupted current, both intra- and extra-laryngeal. After two weeks of daily applications, lasting from three to five minutes, we were rejoiced to get a raucous vocal sound under the stimulus of the battery current.

This, however, was a very uncertain sound, and it was some weeks before there was any sonorous vocalization, excepting under the immediate use of the battery.

About January 1, 1884, there was an intra-laryngeal appearance rudely represented in Fig. 1, with an occasional sonorous note under great effort.

There was ankylosis of the left arytenoid, and no adduction of the left vocal band, excepting a short portion of its anterior end, under the powerful stimulus of the battery current. This ankylosis has gradually yielded to attempted powerful use of the voice, the patient being instructed, after all traumatic inflamma-

FIG. 1.—January 1, 1884.

FIG. 2.—February 1, 1884.

tion had been subdued, to suddenly attempt to shout several times in the day. This gradually loosened the left arytenoid, and it was amusing as well as gratifying to see the first futile attempts at motion in this cartilage, and to notice its slow and almost daily increased motion until, as you will now see, it comes over to nearly its proper place in the vocal effort. The treatment persisted in was essentially a system of vocal gymnastics, with the daily application of the interrupted current, from five to fifteen minutes, only abstaining from its use when there was any evidence of congestion or pain in the larynx.

The vocal powers of this patient have been recovered so far beyond the most sanguine expectations of his physician and family that it presents a tempting field for reasoning as to the structures involved other than the immediate vocal cords themselves. It is true the injuries immediately inflicted upon these bands were not of themselves sufficient to maintain the prolonged adductor paralysis. The course of the ball, fully betrayed by the wounds in the larynx, proves not a matter of any certainty as to the course it pursued in the tissues of the neck on each side of this structure.

The nerves supplying the vocal apparatus are deeply placed in proximity to important blood-vessels.

FIG. 3.—March 1, 1884.

FIG. 4.—April 1, 1884.

That these great blood-vessels were not seriously wounded is quite certain, and that the laryngeal nerves were not

immediately seriously wounded or severed seems almost positive, because the boy spoke after receiving the wound, and the injuries to the nerves were of the nature of contusions, or changes due to traumatic inflammation.

An intra-laryngeal inspection in this case, April 22, 1884 (see Fig. 4), reveals the arytenoid of the left side almost as mobile as its fellow. The epiglottis, which was from the first drawn toward the arytenoid of the left side by reason of contracture of the ary-epiglottic and subjacent tissues, is now symmetrical and almost normal. Upon the right vocal cord, about one half the distance from the anterior end, can be seen what resembles a serration in the free edge of the band.

This serration marks the point of entrance of the missile into the larynx. The left vocal cord is seen to be less mobile, and the free band-like structure is split laterally in its longitudinal axis, so that its measurement, looking from above downward, is four times its normal thickness, especially at that portion next the cartilage.

The ventricle of Morgagni is on this side obliterated by the traumatic distortion, and, indeed, the ventricle is scarcely discernible on the opposite side.

I shall leave any reasoning I might engage in as to the question of concomitant or subsequent lesions in this injury for the discussion by those of my fellows who may feel competent or willing to engage in it. Suffice it for me to say, the boy has regained powers of vocalization, if not equal to what they would have been without the injury (and which I do not assert), yet which are excellent, and ample for nearly all the needs of life other than those of the orator or elocutionist—since in his conversational voice there is little fault that can now be discovered by other than the expert—with a prospect of further intra-laryngeal improvement in the yet somewhat distorted tissues, that gives a reasonable hope of a perfect restoration of all the natural vocal powers of the individual patient.

Dr. Fauvel contributes the following curious case ("Revue mens. de laryngol.," October, 1881):

The patient, ten years before, had received a gunshot wound under the left eye, and medical opinion was divided as to whether the bullet had remained in the head or not. For three months pus and small pieces of bone were discharged through the mouth.

The man had since suffered, at frequent intervals, from acute pain in the head and jaws, and his general health was impaired.

Seven months ago he first felt pain in the throat and in the jaw near the temporo-maxillary articulation and left ear, with pricking sensations, which he compared to a needle plunged in the ear.

Later on the same pricking sensations and pain were felt in the left side of the larynx. There were expectoration of blood, cough, hoarseness, trouble in swallowing, and, finally, aphonia.

Liquids could scarcely pass.

At this crisis laryngoscopic examination was made, and a dark, irregular, lobulated, fungating-looking mass was discovered, filling up the left half of the glottis and concealing the greater part of the left vocal cord.

The other parts of the throat were normal. The tumor most resembled a melanotic growth; but, in consideration of the rarity of such growths in this situation, it was thought

rather that the patient was suffering from the ulcerative stage of laryngeal phthisis. But afterward, as the tumor increased in size and seemed very firm and resisting to the touch, it was diagnosed as osteoma, and its extraction decided on.

Attempts that were made to remove it were not at first successful. The patient passed the night in coughing and vomiting, and, during a fit more violent than the rest, expelled a hard, heavy body, which proved to be a bullet. From this date the patient recovered his voice, and all pain and trouble in swallowing disappeared. Nothing could be seen of the tumor except the slight scar where the bullet had passed through.

On rhinoscopic examination, some small perforations in the upper part of the naso-pharynx were discovered.

Dr. Fauvel, after remarking upon the difficulty attaching to the diagnosis of this case, says that it is equally difficult to explain the manner in which the ball passed downward into the larynx.

He suggests that, having entered apparently below the malar bone, the bullet penetrated obliquely between the ascending ramus of the inferior maxillary and the superior maxillary bone, and became lodged in the basilar process of the occipital bone, in front of the vertebral column and behind the pharyngeal aponeurosis.

The ball, instead of becoming encysted, was probably set free by the surrounding bone becoming necrosed, which would account for the discharge of the pus and spiculae of bone, and the perforations in the naso-pharynx, afterward seen by the rhinoscope.

Yielding to the force of gravity, it then slowly descended in front and to the left of the vertebral column, being concealed from view, first, by the veil of the palate, and afterward by the posterior pillars of the fauces.

When it reached the base of the tongue it changed its direction, and, passing forward and downward, became lodged in the left ary-epiglottidean fold.

Dr. Langmaid writes, April 25, 1884, concerning the soldier Young, whose case is reported in the "Medical and Surgical History of the War," that the patient still wears a trachea tube, and has scarcely any inconvenience from it. He says: "I have examined his throat from time to time; the vocal cords are concealed by a valvular tumor, the base of which presumably occupies the situation of the original wounds, and is, I suppose, the result of an inward prolongation of granulations."

I say valvular tumor, for its action is like that of a pump-valve. Inspiration through the mouth is impossible, but expiration (the external opening of the fenestrated tube being closed by the finger) raises the tumor, and the voice-sounds are easily produced.

Any operative interference with the tumor intra- or extra-laryngeal is firmly refused.

Dr. Samuel Johnston, of Baltimore, sends me a clipping from one of the Baltimore daily papers, of April 21, 1884, which mentions a case of a terrible wound of the neck and throat received by Count von Boreke at Aldie; this officer was once on the staff of Stuart's cavalry in Virginia.

The necessary particulars for our purpose in this case being wanting, I merely mention it as a matter of record for future use if needed.

From Dr. Thomas F. Rumbold I get the following:

"A. M. Groves received a gunshot wound through the larynx December 15, 1879. The missile (a duck-shot, probably No. 4) entered the left side, about one inch posterior to the pomum Adami, passing horizontally and laterally through the larynx, wounding both vocal cords."

The doctor saw the case about seventeen days after the wound was received; the parts were healed, but the marks of the missile were yet perceptible.

The vocal effort, which became aphonic at once after the wound, was, at the doctor's first examination, described as "squeaky." The case was only seen once, and was not made the subject of treatment.

There can be little doubt, however, that the interrupted current would have been beneficial.

Dr. R. B. Tauber, of Cincinnati, kindly sends me the following notes:

"J. S., aged forty-six, was shot in the neck while on a steamboat during the late war; the ball could not be discovered. He complained of dysphagia, was aphonic, and had slight shortness of breath. For twelve years the bullet lodged in his larynx; at the end of that time he consulted me, and, on making a laryngoscopic examination, I found the space of the left sinus pyriformis entirely covered over. I introduced the laryngeal sound, and found the bullet in this cavity lodged very tightly. I removed it, and found it to be a conical .25 caliber, and half an inch long."

The patient measurably regained his voice afterward, and was otherwise relieved of his distressing symptoms.

The voice, however, was described as being imperfect, or, in the language of the doctor, a "monotonous voice."

This case has a striking likeness in its character to the one so graphically detailed by Fauvel, and is worthy of being recorded in its company, deserving a decidedly more extended record:

The second case, given me so courteously by Dr. Tauber, is that of H. L., aged thirty, married, who had syphilis eight years before he was shot in the neck. The bullet entered the right side, under the angle of the inferior maxilla, passed through the epiglottis, injured both arytenoids, and made its exit opposite on the left side, about the sterno-cleido-mastoid muscle. The patient had great dysphagia and dyspnoea; voice not above a whisper; food regurgitated; breath very offensive. Laryngoscopically, the entire larynx was deep-red and congested. Three fourths of the epiglottis were gone, and only a small red stump left. Both arytenoids are at the present time enormously hypertrophied; the stump of the epiglottis has healed. The vocal cords are thickened and reddened, though the patient has regained his voice, and is an expert at swallowing food, which seldom enters the larynx.

My friend Dr. D. N. Rankin kindly reports the case of John Horner, aged twenty-three, soldier in the late war, who was under his care while serving as assistant surgeon in the army:

This man received a gunshot wound, involving the upper part of the larynx, while on picket-duty. The ball entered at the malar process of the right side of the face and passed downward and backward, wounding the nasal passages, tongue, oesophagus, and larynx, making its exit at a point about two and a half inches below the angle of the left inferior maxillary bone.

The patient was nourished by means of the stomach-tube, and finally recovered, with good powers of deglutition and vocalization.

DISCUSSION.

Dr. COHEN.—I have had recent occasion to study the subject of gunshot wounds of the larynx, and have been astonished to find how rare they are in military practice. With regard to the case reported by Dr. Daly, which by that gentleman's kindness I have had the opportunity of examining, I was unable at the time to believe that the ball had traversed the larynx, but thought that it had been deflected around the larynx and had then passed to the point from which it was removed. The missile must have made quite an acute turn to reach that spot after traversing the larynx. The laryngoscopic inspection made by me revealed a larynx much congested and considerably distorted, while the left vocal band was fixed. In view of the subsequent history of the case, as presented in Dr. Daly's report, I am prepared to admit that my former opinion—that the ball had not penetrated the larynx—was an incorrect one.

Dr. LEFFERTS.—There is a specimen of gunshot wound of the larynx in my collection, in the Museum of the College of Physicians and Surgeons, but, unfortunately, without a history. It illustrates a point alluded to by one of the speakers—viz., that a clean-entrance wound could be made through the thyroid cartilage without stellar fracture of that plate. There is in the specimen no wound of exit, the tissues in the interior of the larynx are torn and displaced, and the presence of a tracheotomy incision would show that the ball had remained in the larynx and necessitated tracheotomy for dyspnoea.

Dr. LANGMAID.—With regard to the case under my care, to which Dr. Daly referred, the patient has worn the tube since 1860, and I would modify the statement quoted in one regard: that, if one has to wear the tube a long time, the greatest care should be exercised in its construction. On two occasions this man has suffered difficulty from oxidation of the tube. On one occasion he came from New Brunswick to me at Boston, holding on to the end of a silk thread caught on one portion of the tube, which by oxidation had become severed from the remainder and had fallen into the air-passage. He had made this long journey being in constant fear lest the piece of silk should lose its hold and the portion of the tube fall down the

trachea and block the passage to the lungs. With regard to the shape of the tumor, it is such as to press upon the glottis and act as a kind of valve, and interfere with speech in such a way that the patient seeks relief in conversation by raising the hand to the larynx and making pressure. Fortunately, the tube was inserted low in the trachea.

Dr. Asch.—Cases of gunshot wound of the larynx are extremely rare. I served as a medical officer in the United States Army for twelve years, and acted as Medical Inspector of the Army of the Potomac during the Wilderness campaign of 1864, and no cases of gunshot wound of the larynx occurred in my sphere of duty.

THE ARCHITECTURE OF THE SPINAL CORD, AND ITS RELATIONS TO MEDICINE.

By AMBROSE L. RANNEY, M. D.,

PROFESSOR OF APPLIED ANATOMY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

(Continued from page 600.)

From the gray matter of the cord, bundles may be seen to jut out into the lateral column of either side between the

FIG. 10.—SECTION OF THE CORD BELOW THE MEDULLA OBLONGATA. (Sappey.)

1, anterior fissure; 2, posterior median fissure; 3, gray commissure, much thicker here than lower down; 4, white commissure formed by the decussation of the anterior columns; 5, anterior cornu; 6, posterior cornu; 7, lateral cornu.

anterior and posterior horns. These are commonly designated as the "reticular processes" (*process of Lenhossek*). They do not apparently reach the periphery of the cord, as those that are prolonged into the anterior nerve-roots do.

FIG. 11.—SECTION OF THE CERVICAL ENLARGEMENT OF THE CORD. (Sappey.)

1, anterior fissure; 2, posterior fissure; 3, 3, anterior columns of most authors; 4, 4, lateral columns (these columns in reality pass beyond the anterior cornu, and the anterior columns occupy less space than is here allowed them); 5, posterior columns; 6, posterior commissure (here very narrow); 7, reticulated arrangement of the gray and white matter at the junction of the two cornu; 8, anterior cornu, in which the multipolar cells are distributed into three principal groups; 9, posterior cornu; 10, fifth pair of cervical nerves.

It is probable that some of them contain fibers that connect the vesicular column of Clarke with the direct cerebellar column (see Fig. 21).

Passing through the center of the gray commissure, and extending for the greater portion of the length of the cord, may be seen a small canal—the *central canal of the spinal cord*.* The shape of the central canal of the cord varies in cross-sections made at different levels. In the cervical segments it is oval, in the dorsal circular, and in the lower segments heart-shaped or T-shaped. Its transverse diameter is greater in the cervical and lumbar enlargements than elsewhere. That portion of the gray commissure which lies in front of this canal is sometimes called the "anterior gray commissure," while the portion which lies behind it is called the "posterior gray commissure." In front of the

rior" or "white commissure" is applied. In the cervical segments of the cord the white commissure is thicker than

* This canal is continuous, above, with the *fourth ventricle* of the brain; and the aqueduct of Sylvius is considered by some anatomists as a continuation of it above the fourth ventricle. It presents a pouch, the "ventriculus terminalis" of Krause, at the lower extremity of the cord. Below this pouch it diminishes in caliber and is prolonged into the "flum terminale." It is lined with epithelium throughout.

FIG. 15.—A DIAGRAM DESIGNED BY THE AUTHOR TO SHOW THE AREAS OF THE CROSSED AND DIRECT AND CROSSED PYRAMIDAL TRACTS IN A SECTION OF THE SPINAL CORD, AND THE FIBERS THAT COMPOSE EACH. *a* and *c*, the pyramidal (motor) fibers going from the left cerebral hemisphere to the spinal cord; *b* and *d*, the same of the right cerebral hemisphere.

smaller from above downward, until at last Türk's columns disappear entirely.

The crossed pyramidal column varies in position as well as in size in the different segments of the cord. In the cervical enlargement it occupies a large triangular area in the posterior half of the lateral column, but it does not reach the surface of the cord, nor does it come into contact with the gray matter. It diminishes in size as it passes downward, and ends in the lumbar enlargement, where it reaches the periphery of the cord. It is unquestionably the *great path for all voluntary motor impulses* which are sent out from the brain to the extremities or trunk.

The ANTERIOR ROOT-ZONE is that part of the anterior column which is not occupied by the direct pyramidal fibers or Türk's column. It seems to be composed of fibers which enter the anterior roots of the spinal nerves, and possibly also of commissural fibers that serve to connect the anterior horns of the different segments of the cord.

THE LATERAL COLUMN of each side (exclusive of the crossed pyramidal tract and the direct cerebellar column) is not yet well understood as regards its construction or functions. It contains vaso-motor fibers, and possibly acts as a tract of sensory conduction (Fig. 14).

THE DIRECT CEREBELLAR COLUMN first appears in the upper part of the lumbar enlargement of the spinal cord and increases in size as it passes upward toward the brain. It seems to receive fibers which pass from a group of cells, called Clarke's vesicular column (Fig. 22). The fibers of which it is composed are now believed to pass to the cerebellum directly, i. e., without the intervention of any nodal masses of gray matter.

THE POSTERO-INTERNAL, or GOLL'S COLUMN, is composed chiefly of fibers derived from the posterior horn of gray matter and the gray commissure. It is probably associated with the *conduction of sensation* upward to the brain.

THE POSTERO-EXTERNAL, or BURDACH'S COLUMN, is composed of fibers of the posterior roots of the spinal nerves passing inward to join the posterior horn, and also of *commissural fibers* which connect the posterior horns of the various spinal segments.

Much of our knowledge of the course of fibers within the

spinal cord is no longer speculative. Flechsig has shown that definite tracts of fibers within the spinal cord are *developed at different periods*, as the cut introduced clearly demonstrates, and also that the relative proportion of motor fibers within the direct and crossed pyramidal fasciculi varies with individuals.

We know also that *secondary degeneration* of nerve-tracts occurs when they are *cut off from their so-called "trophic centers"* by traumatism or disease-processes. This degeneration always progresses in the *direction of the currents that are conveyed by the fibers* whose nutrition is affected; hence it progresses downward in the motor tracts and upward in the sensory tracts. Finally, experimental physiology has now determined many facts with an approach to accuracy that were long in dispute, and has thus aided us in properly interpreting symptoms referable to spinal disease. We are now enabled to state positively that the "columns of Goll and Burdach," as well as the "direct cerebel-

FIG. 16.—A DIAGRAM ILLUSTRATING THE DEVELOPMENT OF THE DIFFERENT SYSTEMS OF FIBERS IN THE SPINAL CORD. (Flechsig.)

I, section at level of 3d cervical nerves; II, at level of 5th cervical; III, at level of 6th dorsal; IV, at level of 4th lumbar nerves.

1, principal mass of anterior columns; 2, Burdach's columns; 3, lateral columns; 4, lateral boundary of gray substance; 5, columns of Goll; 6, direct cerebellar columns; 7, crossed pyramidal columns; 7', Türk's columns; v, anterior roots.

Note that Türk's columns disappear in IV; that Goll's columns increase in size from below upward; that the direct cerebellar columns appear in III, and increase in size in II and I; that the crossed pyramidal columns reach the surface in IV; and that the shape of the gray substance differs in all the sections.

lar column," conduct centripetal or sensory impulses, while the "columns of Türk" and the "crossed pyramidal tracts" conduct centrifugal or motor impulses. Some portions of the spinal cord are, however, still in dispute, because their special functions are not as yet definitely ascertained.

The cut of Flechsig's now introduced will enable you to grasp the general direction and distribution of some of the fibers of the spinal cord. It shows (1) the cut ends of the fibers which make up the mass of the various columns, and (2) the course pursued by the motor and sensory fibers which join the cord at the level of the section. Although this cut is purely diagrammatic, it is admirably devised to bring out certain salient points in spinal architecture, to which reference will be made hereafter. The descriptive text of the cut will render it intelligible to the reader.

FIG. 17.—DIAGRAM OF A TRANSVERSE SECTION OF SPINAL CORD IN UPPER HALF OF DORSAL REGION. (Flechsig.)

c, anterior commissure; dc, fibers which pass from the vesicular column of Clarke (vc) to the direct cerebellar tract; P, posterior horn; Pt, crossed pyramidal column; T, direct pyramidal columns; dr, direct cerebellar tract; ar, internal part of anterior root zone; ar', external part of same; pr, posterior root zone; G, columns of Goll; r, reticular formation of spinal cord; a, anterior horns.

FUNCTIONS OF THE SPINAL CORD.

These questions may naturally arise in reference to the previous pages: Why is such a digression from previously accepted terms so universally used, in preference to those more familiar and, possibly, simpler terms of nomenclature? Why should the columns of Türk, Goll, and Burdach be separated from each other when no anatomical line of division seems to have been created? Is the arrangement not a strained attempt to mystify and confuse the medical reader, and does a sufficient ground exist for so great a departure from previous methods of description? In reply to such anticipated questions—and they have been asked of me many times—I would respectfully draw your attention to such points in the physiology and pathology of the spinal cord as will help to show the necessity which existed for such modifications of previously familiar terms, as well as the advantages which are gained by those subdivisions of the cord which are accepted by every specialist on nervous diseases.

In order to properly appreciate many of its functions, the spinal cord must be regarded as a mass of *superimposed segments united together*, rather than as an individual whole. Each spinal segment consists of a disc of the spinal cord with one pair of spinal nerves attached. Such a segment is, to all intents and purposes, an independent structure under certain circumstances. The following diagram will illustrate the construction of a spinal segment.

It will be perceived that each disc of the spinal cord has attached to it one pair of spinal nerves. These arise from it by an anterior or motor, and a posterior or sensory root. Upon the latter is a *ganglionic enlargement*, as is usually the case with all nerves that are sensory in function. It will be seen that the two roots unite to form a so-called spinal

nerve; hence every spinal nerve possesses motor and sensory fibers. Some sympathetic or vaso-motor fibers are also present in spinal nerves. These are not shown in the diagram. Each spinal segment is connected by means of its nerves with

necting links between different segments along the chain. The admirable diagram of Bramwell, which I have modified, illustrate many points in the physiology of the spinal cord better than a long verbal description.

FIG. 18.—DIAGRAM OF A SPINAL SEGMENT, DESIGNED BY THE AUTHOR TO SHOW ITS COMPONENT PARTS.

definite areas of the body. It is capable of receiving sensory impressions from these areas by means of its posterior roots, and of transmitting motor impulses to them in return by means of its anterior roots. The gray matter of the spinal segment, by means of the nerve-cells imbedded within it, can therefore be, under some circumstances, an agent of automatic reflex movement in response to some sensory impression received from without (Fig. 19).

It often becomes necessary, when disease of the spinal cord is suspected, to test the excitability of the different segments of the cord separately, either by stimulation of the skin of different regions or by increasing the tension of certain muscles by a blow upon their tendons, after they have been partially put upon the stretch. The muscular reactions that ensue are known as the "superficial" or "skin-reflexes," and the "deep" or "tendon-reflexes." They will be discussed hereafter.

FIG. 19.—A DIAGRAM DESIGNED BY THE AUTHOR TO ILLUSTRATE THE CIRCLE OF REFLEX ACTION IN A SPINAL SEGMENT. (Modified from Bramwell.)

1, sensory fibers from skin, tendons, joints, etc.; 2, sensory fibers from muscles; 3, motor cell of anterior horn of spinal gray matter (A.H.), joining with 1 and 2; 4, motor fibers given off from 3, and escaping by anterior root to supply the muscles; 5, fiber joining ganglionic cell 3, with the crossed pyramidal tract (P.C.P.) coming from the brain; 6, ganglion on posterior root of spinal nerve; 7, fiber joining 3 with Türek's column (T).

It will be noticed that some sensory fibers (2) reach 3 by passing through Burdach's column (B), while others (1) pass through the posterior horn of gray matter (P) to reach the ganglionic cell (3).

The spinal segments are connected (1) by certain nerve-tracts that pass uninterruptedly to the brain (Fig. 20), and (2) by certain commissural fibers that simply serve as con-

FIG. 20.—A DIAGRAM DESIGNED TO ILLUSTRATE THE PATHS OF MOTOR AND SENSORY CONDUCTION IN THE SPINAL CORD. (Modified from Bramwell.)

D.C., direct cerebellar tracts; C.P., crossed pyramidal tracts; G., sensory tracts of the columns of Goll; T., direct pyramidal tracts, or those of Türek's columns. The arrows show the direction of the conduction, two being centripetal or sensory, and two centrifugal or motor.

(To be concluded.)

THE HISTORIES OF SIX CASES OF OVARIOTOMY.

By GEORGE H. BIXBY, M. D., BOSTON,
FELLOW OF THE AMERICAN GYNÆCOLOGICAL SOCIETY.

CASE I.—December 5, 1881, I was requested by Dr. Henry I. Bowditch to see a patient with him in his office who was suffering from great distension of the abdomen. In order to insure a thorough examination, she was advised to enter the Carney Hospital. Two days later, at the hospital, the following history was elicited: Miss D., aged fifty-seven, a native of Maine, is of

long-lived parentage. The father, whom she resembles, lived to the age of ninety. The mother died of phthisis.

History of Menstruation.—First appearance at sixteen, in normal type; at seventeen she suddenly became stout, but very anæmic, and the menses failed to appear for three successive months. A vigorous tonic treatment in the course of time was followed by a dissipation of the unnatural flesh, the return of the menses, and a complete restoration of the general health. Menstrual life ever after and the climacteric at forty-nine were free from complication. Since her thirtieth year she has lived in the extreme West. There she had typhoid and afterward intermittent fever. For some years past she has resided in the territory of Montana.

At the age of forty-two, on one occasion while bathing, her attention was suddenly directed to a firm, smooth growth in the left ovarian region, of the size of the palm of the hand. She paid no attention to it, and a few weeks later was unable to find it. In her fifty-fifth year the abdomen commenced gradually to enlarge, and, eight months later, materially interfered with respiration and locomotion.

The case was correctly diagnosed by her family physician, Dr. Chalmers, of Ogden, who advised her to return home and seek relief.

November 15th she left Montana for Boston, arriving on the 28th, having traveled thirteen days in coaches and steam-cars without reclining. During this extraordinary journey she partook of only three full meals. This abstinence was necessary in order to control the constant tendency to emesis, caused by the upward pressure of the enormously distended abdomen. Her diet consisted of tea, milk, and fruit. Notwithstanding this remarkable experience, she arrived in Boston a little fatigued, but without injury. At present, a week after her arrival, having fully recuperated, she seems to be in the enjoyment of excellent general health.

Inspection.—The patient is a brunette, above the average stature, with prominent features, a countenance suggestive of firmness, endurance, and a wiry temperament. There is general emaciation, especially of the chest and superior extremities. Abdomen largely distended.

Palpation.—Girth of abdomen at umbilicus, forty-one inches. Percussion elicits universal dullness anteriorly, of which the wave is unbroken, clearness in both flanks, and a solid mass in the left ovarian region, of the size of a fetal head.

Diagnosis.—Cystic degeneration of the left ovary.

Dr. Gilman Kimball, of Lowell, kindly examined the case, and confirmed my views. An operation was advised, and at once accepted. From the foregoing history I felt justified in predicting a favorable prognosis.

January 16th.—Four weeks and two days since her departure from Montana, eighteen days after her arrival, one week in hospital, without any special preparation except an enema the night before, and also half an hour previous to the operation, in the presence of Dr. G. Kimball, of Lowell, Dr. Henry I. Bowditch, Dr. Lyman, Dr. Weston, Dr. Bundy, and Dr. Woodworth, of Boston, and with the assistance of Dr. Bundy, and Mr. H. W. Boutwell, and Mr. C. W. Sparhawk, internes of the hospital, and members of the Harvard Medical School, the operation was undertaken with strict antiseptic precautions. Strength of spray, one to sixty. The latest modification of the Crosby bed, furnished me by Messrs. Codman and Shurtleff, was employed as an operating-table. Length of incision, six inches. There were slight adhesions anteriorly, apparently recent. The tumor consisted of a large central monocyst, inclosing a solid multilocular mass, in the left ovarian region.

The pedicle, of medium length, was transfixed with a needle armed with a ligature of stout English braided silk, each part tied

separately, the ligatures being passed around the whole, and with much force tied a second time, then seared, and finally dropped into the pelvis. The wound, closed with seven silver sutures, was antiseptically dressed, and the patient left indefinitely, as is my custom, on the operating-bed. Weight of cyst and contents, seventy pounds.

Subsequent History.—Briefly: from the first to the sixth day average pulse 100, temperature 99° F. From the sixth to the tenth day, pulse 100, temperature 98°. From the tenth, and after, normal pulse and temperature.

The following points are worthy of separate mention:

1. Urine voided voluntarily from choice from the first day.
2. Fourth day, natural and painless dejections, and ever after with the occasional aid of an enema.
3. Seventh day, removal of stitches; wound healed by first intention.
4. Fourteenth day, removed from the operating-bed and the room. The change might have been made as early as the eighth day.
5. Sat up two hours without discomfort on the nineteenth; walked about her apartment on the twenty-first; was discharged on the twenty-fourth day.

CASE II.—Miss F., aged twenty-eight, a native of New Bedford, consulted me December 28, 1881, for an enlargement of the abdomen. Her father and sister died of phthisis. Her mother, whom she resembles, still lives in the enjoyment of good health. Since her fifteenth year she has worked more or less in a cotton factory, where her labor required much lifting. The catamenia first appeared at sixteen in normal type, three to four days' duration. The function continued normal, and her health was excellent until the twenty-second year, when, no doubt from overwork and confinement in the vitiated atmosphere of the mill, she became debilitated, anæmic, and generally bloated. The menses failed to appear for eight weeks. After a few weeks of tonic treatment her health commenced to improve, and in due time the catamenia returned and she was fully restored to health. This favorable condition of affairs continued three years and a half. In her twenty-sixth year the menstrual interval was reduced to two weeks. In the autumn of 1880 the abdomen commenced to enlarge gradually until June, 1881, when the distension was so great as to interfere with both respiration and locomotion. About this time her family physician, Dr. George T. Hough, of New Bedford, pronounced the case ovarian, tapped, and entirely emptied the cyst.

The beneficial result was soon manifest by improved appetite and digestion, a return of the interval of menstruation to normal, and a corresponding effect upon the general health.

The tumor gradually refilled. At present the abdomen is distended to its utmost capacity.

Inspection.—The patient is a blonde, below the average stature, with an unusually bright and cheerful countenance. There is general emaciation; the girth of the abdomen at the umbilicus is thirty-six inches; percussion elicited dullness anteriorly, with signs of fluctuation with an unbroken wave. In the left ovarian region a smooth, solid mass, of the size of a fist, is easily felt.

Diagnosis.—Cystic degeneration of the left ovary. Operation advised.

The operation was appointed for the 3d, but had to be postponed one week. If the calculation were accurate, this would bring the next menstruation to within less than a week of the operation. As her condition would admit of no further delay, this fact was not considered a bar to immediate operative procedure.

Accordingly, January 10th, without any special preparation, save a laxative the night before and an enema the morning of the operation, in the presence of Dr. Kimball, of Lowell, Dr. S. G. Dearborn, of Nashua, N. H., Dr. Bundy, Dr. Weston, Dr. Woodworth, and Dr. Doble, of Boston, and Mr. H. W. Boutwell, of the Harvard Medical School, interne at the hospital, the operation was undertaken with strict antiseptic precautions. Strength of spray, one to sixty. Length of incision, five inches. There were no adhesions. The tumor consisted of a central monocyte, with a semi-solid mass inclosed, the latter situated in the left ovarian region. Weight of tumor, fifty pounds. The pedicle, of medium length, was unusually broad, and, with the subjacent tissue, uterus, etc., presented unusual vascularity. An attempt was made to enucleate a portion or all of it, but was abandoned on account of the hemorrhage which followed before proceeding very far, but enough had been done to convert the original pedicle into two distinct portions, each of which was transfixed, separately ligated, seared with a black-hot cautery-iron, and dropped. The wound was closed with seven silver sutures and dressed antiseptically, and the patient, like the last, left indefinitely on the operating-bed.

Subsequent History.—January 10th.—Operation ended at 1 P. M. Shortly after recovery from the effects of ether a decided tendency to nausea was controlled by vigorous fanning; 6 P. M., pulse 120, temperature 101° F.; return of nausea; partially controlled by fanning, hypodermic injection, and mustard to the epigastrium.

11th, 9 A. M.—Nausea continued, and occasional vomiting during the night; pulse 110, temperature 100° F. 6 P. M., nausea; vomiting entirely controlled by hypodermic injection and a suppository of opium and belladonna, and absolute rest given to the stomach. Thus far no nourishment by the mouth. Injections of beef-tea and brandy every four hours. Restless, but stomach at rest.

12th, 9 A. M.—Pulse 110, temperature 100° F. 12 M., pulse 120, temperature 100.4° F.

13th, 9 A. M.—Pulse 128, temperature 102.2° F. 12 M., pulse 110, temperature 101° F.; peritonitis suspected; wound and abdomen examined; no signs discovered; menses appeared; cause of rise of temperature accounted for; the catamenia continued four days, during which the pulse averaged 104, the temperature 99.2° F.; after their cessation the pulse came down to 100, and the temperature to 98° F.

From this time the case proceeded without complication.

Points of Special Interest.—1. The vascular condition of the viscera and the sudden and extraordinary rise of temperature were no doubt owing to the approach of menstruation.

2. An unusually abundant flow of apparently healthy urine from the first.

3. Natural dejections daily after the sixth day.

4. Stitches removed on the seventh day; wound found to have entirely closed by first intention.

5. Removed from operating-bed and room on the eighth day.

6. Sat up on the fourteenth, walked about on the sixteenth day.

7. Twenty-fifth day, discharged; rode fifty miles to her home.

CASE III.—Miss C., aged sixty, a native of Ireland, a cook by occupation, entered the Carney Hospital November 1, 1883. She is a brunette of medium stature, looks feeble and careworn.

Menstruation appeared at fifteen in normal type, with a duration of three days, until the fifty-third year, when the climacteric was reached without complication.

Emaciation is general and extreme. The abdomen, of the size of pregnancy at full term, girth thirty-five inches.

Percussion elicits dullness anteriorly, clearness in both flanks, and marked signs of fluctuation.

She first noticed a swelling in the right ovarian region two years before. Its growth has been gradual but constant.

The case was pronounced ovarian, and a portion of fluid drawn by aspiration confirmed the diagnosis.

The chances for an operation were gladly accepted, and the following preparatory treatment was inaugurated:

Ten grains of the bromide of sodium at night; two drachms of the elixir of the tincture of chloride of iron, with gentian, after meals.

At the end of ten days, the general nervous irritability having fully subsided, the bromide was suspended, and the use of drachm doses of citrate of lithium twice daily for ten days concluded the primary treatment.

November 20th.—Ovariectomy was undertaken under strict antiseptic precautions; strength of spray, one to eighty.

Present and assisting, Dr. W. G. Wheeler, of Chelsea, Dr. Michael Gavin, of Boston, Mr. Devine and Mr. Hall, internes of the hospital.

The primary incision was made in the usual manner, each layer of the abdominal wall divided in turn, until the peritoneum was reached. This membrane was so firmly adherent to the ovarian sac that their separation was impossible, necessitating a large opening through both. Firm and extensive adhesions required the employment of the entire hand within the abdomen.

The cyst was raised, the pedicle ligated, clamped, cauterized, and cut free. The abdominal and pelvic cavities were carefully and thoroughly cleansed (a process requiring at least twenty minutes). The ligatures were cut short, the pedicle was dropped, and the wound was closed by silver sutures and antiseptically dressed.

The operation required an hour and forty minutes. At the close of the operation pulse was 130, temperature 101.4° F.

Directions for the Night.—No nourishment of any sort. Stomach to be allowed absolute rest. Enema of brandy and beef-tea every third hour. Urine to be drawn every fourth hour. Against nausea, subcutaneous injections of morphine and atropine. Mustard to the epigastrium; vigorous fanning; ice-pills. Elevated temperature; ice-cap to head; heat to the extremities.

21st, A. M.—Rested quietly. No sign of nausea. Pulse 130, temperature 101° F.

22d, A. M.—Again a quiet night. Pulse 130, temperature 99° F. At 9 A. M., a teaspoonful of milk, at short intervals, was rejected by the stomach; at the end of three hours without nausea.

23d, A. M.—Quiet night under the influence of subcutaneous injections; milk diet resumed and well borne. A troublesome cough annoys the patient night and day.

24th, A. M.—A comfortable night; cough partially controlled by opium. Some alarm felt in regard to the effects of the coughing upon the healing of the wound.

24th, P. M.—Three uppermost stitches removed. At this part, wound healed by first intention; lower portion open, and emitting a purulent, offensive discharge. Wound dressed antiseptically under spray. Extra precautions taken in swathing and dressings. General condition excellent; urine free; abdomen flat.

Examination of chest shows an abundance of fine moist râles.

25th, A. M.—Respiration much embarrassed. Temperature 100°, pulse 120.

25th, P. M.—Somewhat despondent at times; delirious; tongue coated, but moist.

26th, A. M.—Slight general improvement; wound fast healing. Pulse 118, temperature 99°.

27th, A. M.—Slept well. Temperature 98°, pulse 116.

28th.—Pulse 116, temperature 98°. Cough continues unabated. Brandy enema suspended. One ounce whisky every hour by mouth.

29th, A. M.—General appearance not so favorable. Expectoration very profuse. Whisky and nourishment continued in increasing quantities. Condition of stomach continues excellent; rejects nothing, notwithstanding the large quantities of nourishment and stimulants, and the frequency of their administration.

30th, A. M.—Seems very feeble. A poor night; rested only by repeated use of opium. Cough painfully troublesome, taxing her strength at every attack. Temperature 101°, pulse 120.

December 1st, A. M.—Expectorated, during an attack of coughing, two drachms of fresh blood. Another poor night.

Skin cold and clammy; features pinched.

1st, P. M.—Looks haggard and careworn; cold perspiration covers the entire body. State of depression well-nigh amounting to collapse. Can hardly last till morning. Nourishment and stimulants have been pushed all day by the mouth and by enema, and ordered to be continued with the same vigilance during the approaching night.

2d, A. M.—To our great surprise, the patient is still living, but feeble. Nourishment and stimulants continued and increased. Notwithstanding the feeble condition, the stomach receives and retains everything. Recurrence of the depression at the usual time, not far from 4 p. m., but apparently not quite so profound as last night. Cough continues; wound entirely healed.

3d, A. M.—Has taken a large amount of egg-nog, milk, beef-tea, and stimulants during the night; apparently a little brighter, but still feeble. The stomach still faithful to its duties.

3d, P. M.—A recurrence of the state of depression about the usual time, less severe, and of shorter duration.

4th, A. M.—Unmistakable signs of general improvement. Has had a comfortable night, all things considered.

4th, P. M.—Depression at the usual time, but of much shorter duration; general morale of the patient much improved.

5th, A. M.—Decided improvement. Nourishment and stimulants borne without discomfort. At 4 p. m., scarcely any depression; absence of clammy perspiration; cough persists.

6th, A. M.—Fair night. Improvement without interruption from day to day.

9th.—Sat up an hour.

17th.—Walked across the room.

29th.—Left for home, entirely well as far as the operation was concerned, but with the cough persisting.

January 1st.—Upon an examination at home, it was found, in spite of all precautions, that the incessant coughing had produced a well-marked ventral hernia the size of a small peach, which, however, was easily controlled by a properly fitting abdominal supporter. The cough continued, but with less severity.

Points of Especial Interest.—1. The presence of chronic bronchitis months before the operation, assuming, apparently, an acute form almost immediately after.

2. The remarkable condition of the stomach, notwithstanding the feeble state of the general system, to which condition, together with the vigilance of the internes and the Sister in attendance, the patient owes her life. Ex-

cepting in the collapse of cholera, I have never seen a patient reach so low a state and recover.

CASE IV.—Mrs. B., aged forty-three, native of Nova Scotia, of healthy parentage, consulted me June 21, 1883.

Inspection.—She is a tall, robust person, apparently in the enjoyment of perfect health.

Menses appeared at fourteen with regular type, and a duration of eight to ten days. She has had ten children, two miscarriages. She first noticed a swelling in the left ovarian region two months before.

Palpation.—The abdomen is densely covered with adipose tissue. In the right ovarian region a firm, round, regular, smooth mass of the size of a fetal head is easily made out, pediculated, more or less movable from side to side. There is no evidence of fluctuation, nor does it possess the inelastic feel of a fibroid. Bimanual examination fails to detect any connection of the tumor with the uterus.

Diagnosis reserved. I did not see the patient again until the last of September. A most extraordinary change in her condition had taken place. This noble specimen of a woman, whom I had seen two months before apparently in the enjoyment of perfect health, had emaciated to a degree beyond recognition.

Emaciation is extreme and general. The abdomen the size of pregnancy at term, girt forty-two inches, with decided evidence of fluctuation anteriorly. Cleanness in both flanks.

There is no question as to the cystic nature, and an exploratory incision was advised. Still in doubt, the day before that appointed for the operation I removed by aspiration a portion of the contents. Instead of simple ovarian, the fluid was ascitic, of a dark color, and heavily charged with blood and sediment. This discovery postponed the operation indefinitely.

Dr. W. G. Wheeler saw the patient with me a few days later. We arrived at the conclusion that these rather obscure signs hardly justified the radical operation without first tapping clear down. On the following day I removed by aspiration, from the right side, four quarts of bloody serum. Introducing the needle at the left, a small portion of semi-solid, gelatinous matter was only obtained. No reaction followed the tapping. After three days was allowed to get up. She felt much relieved, and went on very comfortably. Even went out to walk and drive.

After three weeks she showed signs of refilling, and had had several distressed spells. The appearance of the catamenia again postponed the operation. Five days after cessation of the catamenia of three days' duration, it having been conclusively shown that relief was impossible by tapping, an exploratory incision was advised. The preparatory treatment had been concluded before the first postponement.

December 11th she entered the Carney Hospital.

On the 12th, in the presence of Dr. Martin Pierce, of New Bedford, Dr. William G. Wheeler, of Chelsea, Dr. George H. Lyman, Dr. W. C. B. Fifield, Dr. Hugh Ferguson, Dr. McKenzie, Dr. Robert Bell, and Dr. Pebble, of Boston, and Mr. Devine and Mr. Hall, internes of the hospital, an exploratory incision was undertaken under strict antiseptic precautions. Strength of spray, 1 to 80. The incision of four inches came down upon the peritonæum, firmly adherent to the sac. It being impossible to separate them, I proceeded at once to make a large opening, hoping thereby for a rapid and complete evacuation. A small portion only escaped, for the contents were made up of a series of cystic formations, containing colloid matter. With the whole hand and arm within the interior of the cyst, the latter were thoroughly broken up and literally scooped out. The size of the tumor thus diminished would

have enabled its passage through the abdominal incision but for the extensive adhesions which held it firmly *in situ*. By gradual and persistent effort the last attachment was finally reached and separated. The adhesions were nearly all of a chronic character, requiring much force to detach them. They occupied the entire anterior wall as far up as the umbilicus. Sweeping round posteriorly and to the right, they extended as far up as the liver and stomach. This protracted and rather violent procedure, added to the free hemorrhage, made a profound impression upon the patient, manifested by a flagging pulse. By the repeated use of brandy, by enema and hypodermically, and by raising the foot of the bed, she soon rallied, and the operation was proceeded with. At length the cyst was raised up attached to a pedicle of medium length and width. Very near its attachment to the cyst there sprang a peculiar flat growth, apparently cartilaginous in its nature, the size of the palm of the hand, suggestive of malignant disease.

Both were clamped and separately ligated, cut free, and cauterized; ligatures left long. The left ovary was found in a condition of cystic degeneration the size of a fist.

This in turn was clamped, ligated, cauterized, and ligatures left long. Sustaining the three stumps well out of the pelvis by means of the long ligatures, the toilet of the peritonæum was undertaken. The sticky, tenacious nature of the contents bid fair to render the task an endless one. After at least twenty-five minutes of sponging in every possible direction, and finally by filling the abdomen full to overflowing with carbolyzed spring water (completing its evacuation by turning the patient well upon one side), both cavities seemed to be entirely free. The three ligatures were now cut short and the pedicles dropped in turn, the left side first. Five silver sutures closed the wound, which was antiseptically dressed. She rallied soon from ether, but, notwithstanding repeated subcutaneous injections, continued restless and wakeful.

13th, A. M.—Pulse 140, temperature 102°. Has been restless the entire night. Occasional naps from opium. Nervous and apprehensive. A tendency to involuntary eructations of hot, tasteless fluid. Urine scanty. On the whole, a poor night.

14th, 2 A. M.—Found her in a peculiarly excitable state. Pulse very feeble. Perfectly conscious, apparently appreciating the seriousness of her symptoms. At 9 A. M. she rallied somewhat, but was still very feeble. At 3 P. M., quite suddenly, she sank without a struggle. She died from exhaustion, there being no evidence of peritonitis or septicæmia.

Remarks.—The rapid progress, duration being less than seven months, was suggestive of the malignant nature. Menstruation occurred, with a duration of several days, when both ovaries were in a condition of cystic degeneration, the right being entirely disorganized, the left, the size of a fist, still showing portions of normal tissue. Aided by this experience in a similar case, I should be tempted, after confirming the diagnosis by aspiration, even in an early stage, to remove the growth. The earliest symptoms which suggested unfavorable terminations were the wakefulness and restlessness for hours after the operation, and the almost complete suppression of the secretion of the kidneys.

CASE V.—Miss D., aged twenty-five, native of Massachusetts, entered the Carney Hospital, October 29, 1883.

The patient is a brunette, a thin, slender person, below the average stature. Her parents still live. On the mother's side an aunt is supposed to have had cancer of the breast.

Menstruation appeared at sixteen, in normal type, with a duration of six days, with an occasional lengthening of the inter-

val. Two years before she first noticed a swelling in the left ovarian region of the size of an egg.

At present the abdomen is the size of pregnancy at term, girding thirty-five inches.

Percussion elicits dullness over the anterior portion of the abdominal wall, clearness in both flanks, with distinct evidences of fluctuation, with an unbroken wave. As an aid to the diagnosis, I removed by aspiration a portion of the contents, which proved to be ascitic, of a dark-brown color.

Diagnosis reserved. The following is a report of the analysis of the fluid by Dr. Gannet, pathologist of the hospital: "Color red; reaction alkaline; albumin $1\frac{1}{2}$ per cent.; moderate amount of sediment containing cholesterolin-cells; numerous large, degenerated fat-cells. The fluid may in all probability be not ascitic, nothing against ovarian, although not sufficient evidence in other points to say absolutely that it is." This report tended to strengthen my doubts entertained at the time of the aspiration, which were based upon the following experience: Some months before I aspirated, and later made an exploratory incision in a case which proved to be malignant disease, in which the fluid was of precisely the same nature as the case under consideration.

The patient was sixty years old. The discrepancy in the ages of these persons, the unquestionable evidences of the cystic nature in the younger, encouraged me to offer her the chances of an exploratory incision.

She was now placed upon the triple preparatory treatment. The latter concluded November 27th. On the 28th the operation was undertaken under strict antiseptic precautions. Strength of spray, 1 to 80. Present and assisting, Dr. W. G. Wheeler, of Chelsea, Dr. Hugh Doherty, Dr. McKenzie, of Boston, and Mr. Devine and Mr. Hall, internes of the hospital. The primary incision was made in the median line three and a half inches below the umbilicus. On reaching and dividing the peritonæum, a gush of brownish-colored fluid followed, disclosing the characteristic pearl-colored cyst, much to the relief and delight of the gentlemen who had watched the case with so much interest and anxiety. The pedicle was clamped, transfixed, ligated, ligatures left long, the cyst cut free, and stump cauterized. A small amount of ascitic fluid in the pelvis carefully sponged out, the ligatures cut short, the pedicle dropped, five silver sutures closed the wound, and an antiseptic dressing completed the operation.

Directions for the night precisely the same as in the foregoing case.

29th, A. M.—Temperature 100°, pulse 109. Several hours of quiet sleep. Milk taken at 4 A. M., and well borne. Abdomen flat.

December 1st.—Temperature 99°, pulse 108. A quiet night. Milk well borne. No signs of nausea. Urine free and of normal color. 6 P. M., complained of pain in the limbs. 9 P. M., catamenia appeared.

2d, A. M.—Temperature 110°, pulse 99.5. Restful night; menstruation persists; all going well.

3d.—Pulse 110, temperature 99°; urine free; no signs of nausea; menses ceased. Removed two upper sutures; at this point wound healed by first intention, lower portion open and suppurating. Remaining sutures removed. Wound antiseptically dressed twice daily.

4th.—Temperature 99°, pulse 108. Wound still discharging. All going on well; food taken and enjoyed.

5th.—Temperature normal, pulse 105. Wound entirely healed; improvement uninterrupted.

13th.—Stood erect for the first time; had sat up days before. At once complained of pain in left limb. Examination showed that the limb was decidedly larger than the right. Sensitive on pressure; general aspect suggestive of phlebitis. Ordered

permanent rest in bed and anodyne liniment; limb to be wrapped the entire length with a flannel bandage.

20th.—Pain and swelling in limb entirely subsided. Discharged well.

CASE VI.—April 6, 1884, I was called by Dr. W. H. Taylor, of New Bedford, to see Mrs. G., suffering from an abdominal tumor. The patient was twenty-four years of age, a native of England, thirteen years in the country. A sister died of phthisis. At nineteen she commenced work in a cotton factory.

Menstruation appeared at fourteen, with normal type, with a duration of seven days. Married at twenty-two, she gave birth to a child one year later. The labor was followed by post-partum hemorrhage. The child was nursed. The convalescence was of short duration, without complication. She soon resumed her labor in the mill, at the same time nursing her child. Five weeks after confinement she noticed a swelling in the right ovarian region, and declared the abdomen had not fully subsided since the birth of her child. The tumor grew apace; the swelling became general; at present, nine months after the discovery, the abdomen is as large as pregnancy at term.

Inspection.—The patient is a blonde, with a bright, hopeful face; below the average stature.

Palpation.—Girth of abdomen, thirty-six inches; umbilicus protrudes; emaciation is general; at the left there are several round, smooth, solid masses the size of a small peach.

Diagnosis.—Cystic disease of the right ovary; operation advised. As a preliminary step, the child was weaned. As the menses had not appeared since confinement, it was deemed advisable to await the return of the function. In the mean time the usual preparatory treatment was carried out.

April 26th.—Dr. Taylor announced the appearance of the catamenia, and their cessation on the 1st of May. She entered the hospital May 6th, riding fifty-five miles by rail. On the 8th—in the presence of Dr. W. H. Taylor, of New Bedford, Dr. J. G. Pinkham, of Lynn, Dr. W. G. Wheeler, of Chelsea, Dr. S. W. Doris, of Winchester, Dr. Leonard, Dr. Ferguson, Dr. Burrell, Dr. Doherty, of Boston, Mr. Hooker and Mr. Bastow, internes—the operation was commenced under strict antiseptic precautions. Strength of spray, 1 to 80. From the excessive distension of the abdomen and the protrusion of the umbilicus, I had fully expected a gush of ascitic fluid to follow when the abdominal cavity was reached. To our great surprise and satisfaction, the cyst-wall presented immediately.

A few fresh adhesions, occupying a space the size of the hand, yielded to slight force. The cyst was now raised, attached to an unusually long pedicle. The latter necessitated ligation in three distinct parts, and finally all were included with one ligature, making a single pedicle. The unusually brief process of cleansing the peritonæum having been concluded, the wound was closed with five silver sutures and antiseptically dressed.

The subsequent history can be told in comparatively few words.

Up to the third day pulse continued 110, temperature 101°. Urine free and of good color; not the slightest evidence of nausea. At 12 m. of the third day an extraordinary change became evident. Pulse rapidly rose to 130, temperature to 103.4°. Nausea and vomiting ensued, accompanied by repeated defecations. Menstruation occurred on the third day. On the fourth day there was a sudden fall of temperature and pulse—viz.: pulse 110, temperature 101°. From this on improvement was uninterrupted; the sutures were removed on the seventh day. She sat up on the tenth, walked about the apartment on the 13th. Left for home on the 20th, three weeks less one day.

Clinical Reports.

ROOSEVELT HOSPITAL.

CLINICAL REMARKS BY HENRY B. SANDS, M.D.

Pelvic Abscess.

GENTLEMEN: We have no operations to-day as important as those you have witnessed within the past two weeks, but there are one or two interesting cases from which, perhaps, we may derive some profitable instruction.

This patient, a woman aged twenty-six, married, came here a few days ago to be treated for a swelling in the abdomen. Her history is somewhat meager. She has had four children, the last one of which was born seventeen months ago. Her monthly periods have been regular. Five months ago, after lifting some heavy tubs of water, she felt a pain in the hip on her right side, and for a few minutes was unable to walk. Since then the pain has continued, and she has had more or less sweating. She is unable to assign any cause for the symptoms, unless it be an injury produced by the heavy lifting.

As you may see, a prominent swelling occupies the right iliac fossa. This swelling fluctuates, and an exploration, made with an aspirating-needle, has demonstrated the presence of thin, flocculent pus. Beyond this point the case has not been studied; but now, while the patient is under the influence of ether, we will examine her more carefully and thoroughly, and try to ascertain the cause of the abscess. I am able to flex the thigh at the hip joint without any difficulty, except that the limb can not, without undue force, be fully extended; the other movements are unimpeded. I am unable to discover crepitus, which might exist if the abscess were due to morbus coxarius. I have known such cases in which a perforation of the acetabulum has led to the formation of a large pelvic abscess pointing in the iliac region. This tumor seems to fill the iliac fossa and to extend above it, lying between Poupart's ligament and the umbilicus. It is a firm, rather elastic swelling, except at one point, about one inch above Poupart's ligament, where there is distinct fluctuation. This fluctuation is caused by matter, as the exploration has proved. We have, then, a case of abdomino-pelvic abscess, with very thick walls; but the origin of the disease is still uncertain. Yesterday I examined the spinal column, but could not discover any tenderness or projection indicating caries. Introducing my forefinger into the vagina, I find the uterus movable, but displaced toward the left side by the tumor, which can be appreciated as a firm, smooth, and convex mass. No additional information is gained by digital exploration of the rectum. Whether the abscess is idiopathic or is dependent upon caries of the spine or pelvis, or whether, as occasionally happens, it is developed in a malignant growth, can not be determined without a free incision. This, I believe, should be made, in order to check the rapid progress of the abscess which has recently been noticed, as well as to allay the severe pain caused by the tension of the sac.

In opening an abscess by cutting through the anterior abdominal wall, you must proceed with caution, otherwise you will be liable to wound the peritonæum, or even to cause the contents of the abscess to escape into the peritoneal cavity—an accident that might be followed by fatal peritonitis. Often, it is true, the serous membrane is stripped off as the abscess grows, so that there is no risk of wounding it. But, if the peritonæum has not been thus displaced, the accident referred to will be avoided only when adhesion has occurred between the parietal layer and that which covers the abscess. In case the integument is red, shining, and adherent, you may without hesitation

thrust a knife directly into the cavity, and, in withdrawing the instrument, enlarge the opening to the extent you deem requisite. If, however, there are no signs of pointing, you must proceed cautiously, and operate in the same manner as when you tie an artery in continuity, or cut down upon a strangulated hernia. By adopting this method, and carefully recognizing, before dividing them, the several layers composing the abdominal wall, you will generally be able to ascertain whether the peritonæum lies in the track of the knife, and, if so, whether it is adherent or not. When the adhesion is firm, the abscess should be opened; but, if the tissues exhibit little or no evidence of plastic infiltration, and especially if the peritonæum can be raised with a forceps, or made to glide over the abscess-wall, the knife should be laid aside and the completion of the operation postponed to a more favorable period. In many cases the adhesive process is hastened by what has now been done, so that, a few days later, the abscess may be safely opened, unless, as often happens, it ruptures spontaneously, discharging its contents through the wound. Even when caution is observed, however, the peritonæum may be accidentally wounded. In a case in which I once committed this error I seized the peritonæum, which I had only punctured, and closed the opening by a fine silk ligature. No mischief followed the accident, and subsequently the abscess broke in the operation-wound. In another case—also a perityphlitic abscess—which occurred in the practice of one of my friends, a more extensive wound of the peritonæum was made, requiring a suture in order to close it. In this instance, also, no harm was caused by the accident, and a few days afterward the matter was safely evacuated by an incision made at the lower angle of the wound in the abdominal wall. Such cases prove that, even when the peritonæum has been unintentionally divided, no disaster necessarily follows, provided the wound in the serous membrane is carefully closed, either by suture or ligature. But if the operator should be so unfortunate as not to discover his mistake in time, and should proceed to incise the abscess, its contents would almost inevitably enter the peritoneal sac and set up fatal inflammation there.

I have now opened the abscess, and have experienced no difficulty in performing the operation, because I found the tissues infiltrated with plastic material and adherent to the abscess-wall. About six ounces of thin, flocculent pus have been discharged, and, upon introducing my index-finger into the cavity, I discover that its walls are exceedingly thick and uneven, being quite unlike the sac of an ordinary chronic abscess. I am inclined to believe that the essential disease in the present case is a malignant new growth, which has accidentally undergone suppuration, and, as the tumor is extensive and is firmly attached to the pelvis, any attempt to remove it would be injudicious. Nothing remains to be done, therefore, beyond washing out the cavity with a solution of mercuric bichloride (1-1,000), inserting a drain, and applying an absorbent antiseptic dressing. Small fragments of the abscess-wall have been torn off, and will be subjected to microscopic examination, in order to settle the question of diagnosis. Meanwhile, the woman will probably obtain temporary relief, and the burrowing of matter will be arrested.

[NOTE.—The patient was taken to her home a fortnight after the operation, which afforded some relief to pain. The pieces removed from the wall of the abscess were found to have the structure of carcinoma.]

Yellow Fever.—The Paris "Temps" has information of two cases at the mouth of the Gironde. The Surgeon-General of the United States Marine-Hospital Service has news that the disease is no longer epidemic in Rio de Janeiro.

Book Notices.

On Bedside Urine Testing, including Quantitative Albumin and Sugar. By GEORGE OLIVER, M. D. Lond., M. R. C. P. Second Edition. London: H. K. Lewis, 1884. Pp. 128.

The object of this little book is to facilitate the examination of urine at the bedside by means of test-papers which the author has devised, made from ordinary filtering paper charged with solutions of substances which constitute delicate tests—such for example, as picric acid, potassio-mercuric iodide, sodium tungstate, and potassium ferrocyanide for albumin. The design of the book is thoroughly praiseworthy, and we do not doubt that it will prove of great service to the practitioner, especially in the country.

BOOKS AND PAMPHLETS RECEIVED.

Hooper's Physician's Vade Mecum: a Manual of the Principles and Practice of Physic, with an Outline of General Pathology, Therapeutics, and Hygiene. Tenth Edition, revised by William Augustus Gay, M. B. Cantab., F. R. S., etc., and John Harley, M. D. Lond., F. L. S., etc. Vol. II. New York: William Wood & Co., 1884. Pp. 358. [Wood's Library of Standard Medical Authors.]

Education the Means for Unifying the Medical Profession and Strengthening the State Medical Association. By R. A. Kinloch, M. D., President of the South Carolina Medical Association. Delivered at Florence, S. C., April 22, 1884. [Reprint from the "Transactions of the South Carolina Medical Association."]

A New Method of Treating Chronic Glaucoma, based on Recent Researches into its Pathology. By George Lindsay Johnson, M. A., M. B., B. C. Cantab., etc. With Illustrations. London: H. K. Lewis, 1884. Pp. 48.

The Diet Question, giving the Reason Why. By Susanna W. Dods, M. D. New York: Fowler & Wells, 1884. Pp. 99.

Contributions to the Anatomy and Pathology of the Nervous System, based on Researches conducted in the Private Laboratory of E. C. Spitzka, M. D. Series iii, No. 2. Nodular Tumor of the Corpus Callosum. By Francis A. McGuire, M. D., of New York. Pp. 7.

Directions for the Antiseptic Treatment of Wounds, as employed at Professor Billroth's Clinic. Arranged for Students and Physicians, by Dr. Victor R. v. Hacker, Assistant Surgeon at Professor Billroth's Clinic in Vienna. Translated by Frederic W. Taylor, A. B., M. D. Boston: Cupples, Upham & Co., 1884. Pp. 41. [Price, 50 cents.]

Consideraciones sobre la Técnica Histológica Moderna, su Importancia y Aplicaciones. Memoria presentada y leída en la Sección de Histología de la Academia Médico-Quirúrgica Española, en la Sesión Científica celebrada el día 30 de Enero de 1883, por el Académico de Número Doctor Leopoldo Lopez García, Presidente de dicha Sección, etc. Segunda Edición. Madrid: Establecimiento Tipográfico del Hospicio, 1884. Pp. 41. [Price, 1 peseta.]

The Objects of Dermatological Classification, with especial reference to Auspitz's System. By Edward Bennet Bronson, M. D., Professor of Dermatology in the New York Polyclinic. [Reprint from the "Journal of Cutaneous and Venereal Diseases."]

Memoria sulla Cura dello Scollamento della Retina (Iridectomia). Pel Dottore Raffaele Castorani, Professore di Oftalmiatria e Clinica Oculistica nella R. Università di Napoli, etc. [Reprint from the "Resoconto della R. Acc. Medico-Chirurgica di Napoli."]

Correspondence.

LETTER FROM WASHINGTON.

Sanitary Matters in Congress.—The National Museum.—Precautions against the Importation of Diseased Cattle.—Medical Provisions for Seamen.—A New Medical College.—The "Index-Catalogue."

WASHINGTON, July 1, 1884.

SINCE I last wrote you, medical matters in Congress have not been numerous, but have been quite interesting. The House of Representatives has voted the repeal of the National Board of Health, and an appropriation of \$10,000 for the Gulf quarantine at Ship Island. The matter is now before the Senate for final action. The Surgeon-General of the Marine-Hospital Service has asked Congress to appropriate \$7,200 to pay inspectors to be stationed in foreign countries and attached to the consulates where epidemics exist. This action was taken with reference to the probable spread of cholera in France and in Europe generally. The singular subjugation of England by her commercial interests is viewed with alarm at this juncture by sanitarians. No reports of any precautions against the spread of cholera in England have been noted. The joint resolution to print additional copies of the "Medical and Surgical History of the War" and the "Index-Catalogue" has passed both houses, and was finally approved by the President June 20th. The resolution provides for sale of the volumes to the public at cost price, with ten per cent. added. On the same day the President approved the act to authorize the National Academy of Sciences to receive and hold trust funds for the promotion of science and for "other purposes." The "other purposes" seem to provide for such disposition of funds as may be necessary to carry out the will of any donor of funds.

The Treasury Department has issued the following circular in relation to samples of drugs, etc., for the National Museum. This is a notable step, looking toward the perfection of the collection:

"WASHINGTON, D. C., June 21, 1884.

"To Collectors of Customs and others:

"This Department is informed that the United States National Museum at Washington has established a Department of Materia Medica, in which it is proposed to preserve and exhibit specimens of substances

used for medical, surgical, or pharmaceutical purposes, by the people of all countries, whether civilized or savage. The collection now includes more than three thousand specimens.

"It has been suggested that customs officers at the principal ports of entry might properly forward to the Museum, from time to time, small samples of such medicinal products as may be imported, and as they may believe will be of interest to the student or expert.

"In referring to the matter, the director of the National Museum states that its officers would be glad to receive not only specimens of drugs, but also of fibers and textile fabrics, food substances, and, in fact, of any and all of the materials of commerce, it being desirable to have not only typical examples of each kind of object, but examples from each country whence they are imported into the United States.

"The appraising officers are requested to forward to the Museum portions of samples of the character mentioned, which can be spared without great inconvenience and can properly be furnished.

"The Museum, of course, will be required to pay any expense incurred in the transmission of the samples other than that for postage."

The Treasury Department has also issued a new circular in regard to the importation of cattle and the Treasury quarantines. The lines are strongly drawn against the importation of cattle diseases.

The new Merchant Shipping Act, which was approved by the President June 26, 1882, regulates in an effectual manner the shipment and discharge of seamen; it places the power to make regulations for shipping commissioners in the hands of the Secretary of the Treasury. It will now be possible to have a thorough physical examination of the crew before shipment. It prohibits the payment of advance wages, and directs the enlargement of the "slop-chest." It abolishes the Marine-Hospital tax, and provides that the service shall be hereafter supported from the tonnage tax. Altogether the bill is a great advance on the Shipping Act of 1872, which it is designed to supplant.

It is observed that the recent announcement of the Georgetown Medical College provides that an examination in the branches of an English education will be required as a requisite for admission.

A new medical college has been announced, with the following as the faculty: John T. Winter (M. D., Georgetown, 1870), professor of materia medica; Howard H. Barker (M. D., Georgetown, 1870), professor of obstetrics, dean of the faculty; Thomas E. McArdle (M. D., Georgetown, 1879), professor of surgery; Samuel S. Adams (M. D., Georgetown, 1879), professor of the theory and practice of medicine; G. W. Cook, M. D., professor of physiology; and G. William West, M. D., professor of anatomy. M. F. Cuthbert (M. D., Columbian, 1883) was elected professor of chemistry, but it is understood he has declined to serve. The new venture is to be called the Medical Department of the "National University." There has been a law department of this university in existence for some years, but the collegiate and other "departments" only existed on paper in the charter of the institution. The well-known energy of the young men composing the "medical department" is an earnest that they will do much toward bringing up the new college to the high plane occupied by its sister institutions in this city.

It is announced that the fifth volume of the "Index-Catalogue" has been sent to the press. This brings the work down to the word "Heart," and includes all works under that title.

THE TREATMENT OF ASPHYXIA.—Dr. B. Howard, lately repeated in Paris a demonstration that he had given before the Royal Medical and Chirurgical Society, of London, the main point of which was to show the inadequacy of the procedure of dragging the tongue forward, and to prove the complete efficiency of forced extension of the head and neck. The "Progrès Médical" remarks that M. Verneuil recognized the truth of Dr. Howard's statements and the importance of their applications.

THE

NEW YORK MEDICAL JOURNAL,

*A Weekly Review of Medicine.*Published by
D. APPLETON & CO.Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JULY 12, 1884.

THE NEW YORK STATE BOARD OF HEALTH'S MONTHLY BULLETIN.

We have received the first issue, covering the month of May, of a new publication that seems to us likely to prove of great interest and importance to those who have to deal with public health matters in the State of New York. It is entitled the "Monthly Bulletin of the New York State Board of Health," and gives abstracts of the reports of deaths and their causes in the eight districts into which the board has divided the State for the purpose. These districts are as follows: 1. The Maritime District, including the city of New York, together with Long Island, Staten Island, and Westchester County; 2. The Hudson Valley District, comprising all the counties on either side of the river, from Westchester County up to and including Washington County; 3. The Adirondack and Northern District, being the northern section of the State—the counties of Warren, Hamilton, Essex, Clinton, Franklin, St. Lawrence, Jefferson, and Lewis; 4. The Mohawk Valley District, taking in the counties of Schenectady, Schoharie, Montgomery, Fulton, Herkimer, and Oneida; 5. The Southern Tier District, including the seven counties lying along the southern boundary of the State; 6. The East Central District, made up of the counties of Sullivan, Delaware, Otsego, Madison, Chenango, Onondaga, and Cortland; 7. The West Central District, including the counties of Cayuga, Tompkins, Seneca, Schuyler, Ontario, Yates, Livingston, Genesee, and Wyoming; 8. The Lake Ontario and Western District, being the counties of Oswego, Wayne, Monroe, Orleans, Niagara, and Erie.

This division of the State into sanitary districts seems well contrived as regards both geographical features and adaptability to comparisons relating to meteorological and other allied conditions. While this arrangement groups the returns in a convenient and useful way, the condensation of the statistics has not been carried to such an extent as to blot out the individuality of particular localities of any considerable importance, for lists of towns, varying from six to twenty-one in number, are given under the different district headings. Under the head of the Maritime District, for example, we find the following localities mentioned, each with its own returns: New York, Brooklyn, New Lots, New Utrecht, Long Island City, Newtown, Oyster Bay, Hempstead, North Hempstead, Jamaica, Southold, Southampton, Northfield, Yonkers, Westchester, Mount Pleasant, Rye, Sing Sing, and the "rest of the district." The latter phrase closes the sub-headings under each of the district titles, and we presume it covers the sparsely populated districts from which a segregation of the returns would lead to the insertion of figures too small to be of service for statistical purposes.

The tabular statement gives the population of each locality, its total number of deaths, the death-rate, the number of deaths of persons under five years of age, the percentage of such deaths to the whole number, and the various causes of death, as follows: Cerebro-spinal fever, typhus, typhoid fever, malarial diseases, small-pox, scarlet fever, measles, erysipelas, whooping-cough, croup and diphtheria, acute respiratory diseases, consumption, puerperal diseases, diarrhoeal diseases, non-diarrhoeal diseases of the digestive system, diseases of the urinary system, diseases of the circulatory system, diseases of the nervous system, cancer, accidents and violence, old age, and unclassified causes. It speaks well for the carefulness with which the table is made up that we find in a foot-note an explanation of the occurrence of five deaths from "accidents and violence" in the town of Waterford, having a population of only 4,826—the occasion being a boiler explosion. On the other hand, pains have been taken to note the manifest incompleteness of the returns from the large town of Troy.

THE ALBANY MEDICAL COLLEGE.

Among many recent indications of the progressive spirit which actuates the governing body of the Albany Medical College, the graduates of which occupy with credit many positions of honor in the profession throughout the country, some of the most striking are to be found in the report of the proceedings of the eleventh annual meeting of the alumni association, a copy of which has lately reached us. The pamphlet gives abundant evidence of lofty purposes and substantial achievements on the part of the college and on the part of the alumni association. The most noteworthy, perhaps, is the fact that the association has so soon been enabled to follow the example of a like association connected with the College of Physicians and Surgeons in this city, and provide for an annual course of alumni lectures. The first course will be given by an alumnus of the Albany Medical College, Professor William H. Thomson, of the Medical Department of the University of the City of New York. The lectures will be delivered next March, the subject being "The Germ Theory of Disease." We are glad to learn that the expense of the first course has already been provided for, and we feel confident that the committee will encounter no serious difficulty in securing contributions ample to make like provision for succeeding courses.

There was another and an exceptional aspect to this meeting of the alumni association, and one which, however the unthinking may be inclined to dismiss it as being of a sentimental character, seems to us of more hopeful augury for the college than any mere material prosperity, for it argues a heartiness and an *entente* among all connected with the institution more potent than any consideration of policy or enthusiasm, as well as a status of the profession in Albany upon which we may all look with satisfaction. We refer to the tinge of sorrow cast over the whole proceedings by the loss that had been sustained by the faculty and the association during the year in the death of the president of the latter, the late Dr. Mosher. It is not alone in the formal eulogies spoken by Dr. Murray, Mr. McKel-

way, and Dr. Ward that the deep feeling of the meeting is to be perceived; it stands out unmistakably in the brief remarks of welcome made by Professor Perkins in behalf of the faculty. Mr. McKelway's address, coming from a man who not only is not connected with the college, but is not a member of the profession of medicine, was the particular feature to which we have referred as showing an enviable status of the profession with the community in Albany. To appreciate its full significance in this regard, we should remember that but a month had elapsed since the same gentleman paid a most touching tribute to Dr. Mosher, and that without having been set down for any such part, at the annual dinner of the Medical Society of the State of New York; which fact, if any token were needed, goes to show the heartiness that moved him, and incidentally the feelings of a representative layman toward the medical profession of Albany. From all points of view, therefore, the position of the Albany Medical College is one that calls for praise and congratulation.

MINOR PARAGRAPHS.

ALBUMEN AND ALBUMIN.

THE "Medical News," of Philadelphia, discusses the propriety of spelling albumin with an *e* or with an *i* in the final syllable, and concludes that, although uniformity is desirable, there is not "sufficient reason for English writers deviating from the original well-founded spelling of the word" (meaning *albumen*). Were uniformity all that was aimed at by the use of the word albumin, the conclusion reached by the "News" would be more justifiable than it is in view of the actual facts. The simple truth is that albumen (German *Eiweiss*) means white of egg, while albumin has for many years been applied to the proximate principle (German *Eiweissstoff*). If the authors of the "United States Dispensatory" had heeded this distinction, it is not likely that the fifteenth edition of that work would have contained this remarkable sentence, which is to be found on page 1080: "It contains, according to Dr. Bostock, in 100 parts, 85 of water, 12 of pure albumen, 2.7 of uncoagulable matter, and 0.3 of saline substances, including soda with traces of sulphur." In other words, there is only twelve per cent. of albumen in albumin! We confess that the word albumin is of faulty formation; albuminin would be more in accordance with the correct mode of constructing such words, but, unfortunately, albuminin has already been applied to another substance, namely, the material of the cells which inclose the white of an egg. As the matter stands, therefore, to the query, Albumen or albumin? we would answer, Albumen and albumin—the former in pharmacy, when white of egg is meant, and the latter in speaking of what we test for, which certainly is not white of egg.

TWO VIEWS OF THE PROBE.

BEARING in mind the decided views put forward by Dr. Amidon in a paper recently read before the Academy of Medicine, an abstract of which was given in our issue for June 14th, those of our readers who may chance to read Dr. J. M. Keller's presidential address before the Arkansas State Medical Society at its ninth annual meeting will be likely to be struck with the diversity of the sentiments expressed by these two gentlemen. Speaking of the use of the probe in penetrating wounds of the visceral cavities, Dr. Keller says: "Men have learned to know that to pass the probe beyond the chest wall or the abdominal wall with any hope of tracking the missile which has made the

wound, without reproducing the danger, is as absurd and foolish as an undertaking as attempting to find the needle in the straw stack."

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 8, 1884:

DISEASES.	Week ending July 1.		Week ending July 5.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	4	0	1	0
Typhoid Fever.....	15	4	9	3
Scarlet Fever.....	38	15	42	13
Cerebro-spinal meningitis. .	3	3	4	4
Measles.....	171	30	171	32
Diphtheria.....	43	23	34	18

The Cholera in Europe.—The Asiatic origin of the epidemic in Toulon and Marseilles is now practically unquestioned, and Dr. Koch is said to have given it as his opinion, based upon a study of the Toulon cases, that it originated in the extreme East. Both the French people and their neighbors have become thoroughly aroused to the danger of the situation, and the general expectation seems to be that the disease will spread over Europe, and probably reach this country before the close of the summer. In consequence of this feeling, there have been some signs of panic in certain parts of France, and the Parisians are reported to have left for the seaside in unexampled numbers. There have been reports of a few cases of cholera in Paris, but thus far none of them have turned out to be genuine. Passengers arriving at Paris from infected places are disinfected before being allowed to enter the city.

At Toulon, the seat of the first outbreak, it is thought that the virulence of the disease has abated somewhat, but that it will persist with a diminishing mortality to the close of the season, causing not more than a thousand deaths in all. Up to the 8th inst. there had been one hundred and fifty-four deaths. On the 6th there were one hundred and thirty patients in the hospitals, most of whom were not considered to be in great danger. Among the victims is a naval surgeon, Dr. Borel.

In Marseilles the outlook seemed more encouraging on the 2d of the month, and it was thought that there would be no occasion to postpone the *fête* of the 14th, in celebration of the fall of the Bastille, but the next day things took an unfavorable turn again, six thousand people were stated to have fled, and the authorities decided to omit the *fête*. According to the dispatches, the next two days were marked by a decided abatement, but on the 6th and 7th of the month there was another decided recrudescence, and it was then found that infected vessels were entering the port. On the 8th the alarm was increasing, and it was stated that nine tenths of the victims were women. On the 9th a number of policemen became frightened and tendered their resignations. They were dismissed the force. There have been rumors of a few cases at Lyons, Nice, and Aix, but they do not seem to have been substantiated.

Stringent precautions against the spread of the disease are being taken all through the south of Europe. Italy guards the French frontier, and stops refugees from Marseilles. Passengers by the Mont Cenis tunnel are detained five days. A dispatch from United States Vice-Consul-General Wood, at Rome, to the State Department, dated July 4th, said: "All vessels to Sicily and Sardinia, ten days' quarantine; to other Italian ports, quarantine from French ports only. General health excellent, but a case of cholera has occurred. It was in quarantine at Piedmont." The Italian Government is reported to have prevented

the Sicilians from refusing a landing to English vessels. According to the Paris "République française" of July 9th, cases of cholera had occurred at Valencia, Barcelona, Rome, Leghorn, and Viterbo, and that paper therefore calls upon the French Government to declare a quarantine of vessels from Spain and Italy. The Spanish quarantine of English vessels is maintained, although the British Government is understood to have protested. At Gibraltar the British forces are said to have compelled the withdrawal of the Spanish sanitary cordon beyond the middle of the neutral ground. Portugal has ordered a quarantine of all English vessels. At Geneva passengers from Toulon and Marseilles are disinfected at the railway station. Notwithstanding all that the English have said against the quarantine policy, a London dispatch dated July 8th states that a tugboat with quarantine officers on board is scouring the English Channel with orders to board vessels bound for Cardiff, especially vessels from France and Spain.

Our own Government is taking proper precautions, and that this course is in the highest degree necessary is shown by the fact that information has been received that great numbers of French refugees are on their way to this country on other than French vessels. The Post-Office Department has asked the British mail officials to separate and disinfect the mails from France by way of Great Britain, but, according to present advice, either the request has been misunderstood or the British authorities do not consider it incumbent on them to comply with it, and therefore arrangements are making to disinfect the mails on this side of the Atlantic. The necessity of personal and municipal sanitation is urged upon the attention of local officials by a circular recently issued by the State Board of Health of New York. The Mexican Government has ordered a quarantine of vessels from France on the Gulf Coast.

Small-pox seems still to be on the increase in London, and the Liverpool correspondent of the "Lancet" expresses the fear that an epidemic of the disease is impending in that city.

The Health of Connecticut.—The State Board of Health's monthly report for May, prepared by the secretary, Dr. C. W. Chamberlain, of Hartford, gives a tabular statement of the deaths from the most noteworthy causes in nine of the large towns of the State, and this is followed by careful and interesting comments upon the returns. It appears that for two or three years past, contrary to the usual state of things, the mortality from pneumonia has been greatest during the month of May, but that the indications are that the excess will be considerably reduced this year, in consequence, as the secretary thinks, of the increased carefulness with which attacks of bronchitis have been met which otherwise would have been likely to develop into broncho-pneumonia. "When pneumonia is prevalent or in season," the secretary adds, "an attack of bronchitis merely, or what appears as such, is not to be despised." Although decreasing, diphtheria still lingers in Hartford, where it caused nine deaths during the month. Except in a few localities, malarial diseases have continued to decrease.

Sanitation in Illinois.—At the regular meeting of the State Board of Health, held at Springfield on the 2d inst., the secretary, Dr. John H. Rauch, presented an elaborate report reciting the transactions of the board during the three months, and discussing the probabilities of the prevalence of cholera and other pestilential diseases in this country during the present year. After the reading of the report, the board adopted the following resolutions:

Resolved, That the importance of the study of practical anatomy, as a foundation for surgical knowledge and skill, demands

that the supply of material for this study be more definitely regulated, and its necessity recognized by law, and that the Illinois State Board of Health respectfully urges the attention of law-makers to these considerations.

Resolved, That the increasing prevalence of small-pox in London and elsewhere, indicating a probable renewal of the epidemic tendency, and its frequent introduction into Illinois from neighboring States within the past few months, make it desirable that vaccinal protection be secured as fully as possible in every portion of the State; and to this end the secretary is hereby authorized to call the attention of the sanitary authorities and others to the subject, and to take the necessary steps to push the further enforcement of the School-Vaccination Order of the board, so that all new scholars, and those who have not heretofore fully complied with its provisions, may be properly protected against small-pox before the advent of cold weather.

Resolved, That, while epidemic cholera may be excluded from this country by thoroughly enforced quarantine regulations, yet the best attainable sanitary condition of every locality in the State should be secured, so that, in the event of Asiatic cholera effecting an entrance, notwithstanding quarantine, the disease may be met and fought under the most favorable circumstances. The secretary is, therefore, hereby authorized to take such action as, in his judgment, will most promptly attain a thorough sanitary organization of the State and the adoption and enforcement of the measures necessary to improve its general sanitary condition.

Epilepsy Mistaken for Hydrophobia.—A man having fallen in an epileptic fit lately, in the region of the Five Points, three policemen, as the story is told in the daily papers, bound him with cords to an awning-post, gagged him, and stood over him with drawn clubs, ready to administer promptly to any symptoms of hydrophobia that he might show on recovering consciousness, they having been told that the man had been bitten by a dog.

Recent Changes in European Faculties.—According to the "Progrès médical," Dr. Rudolf Boehm, director of the Pharmacological Institute of Marburg, has been called to Leipsic as professor of pharmacology and hygiene. Dr. Schauta, extraordinary professor of obstetrics and gynecology at Innspruck, has been made ordinary professor of the same branches. Dr. Le Fort, professor of operative surgery at Paris, has been transferred to the chair of clinical surgery, succeeding M. Gosselin. At the same faculty, the course in medical chemistry, formerly given by the late Professor Wurtz, has been intrusted to M. Hanriot, an *agrégé*. The Prague faculty have resolved to nominate the following candidates to succeed Professor Hasner, retired: Becker, of Heidelberg; Fuchs, of Liège; and Sattler, of Erlangen. Dr. Becker is said to have declared that he will not accept the position unless the ophthalmological clinic is reorganized in conformity with the demands of the present state of science. Only one nomination having been made for the chair of anatomy, the Minister has returned the name of the nominee, Dr. Aeby, of Berne, and directed three nominations to be submitted to him. According to the "Union médicale," M. Duplay, professor of external pathology at the Paris faculty, has been transferred at his own request to the chair of operative surgery, made vacant by the transfer of M. LeFort.

Sanitary Appointments in Paris.—The "Union médicale" announces that M. Brouardel has been nominated president of the consulting committee of hygiene, and M. Berthelot president of the committee on departmental and municipal laboratories, the latter in place of the late M. Wurtz.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from June 29, 1884, to July 5, 1884:*

HARTSUFF, ALBERT, Major and Surgeon (Fort Riley, Kan.).

Granted leave of absence for one month, with permission to apply for one month's extension, to take effect when his services can be spared. Par. 6, S. O. 180, Headquarters Department of the Missouri, June 25, 1884.

MIDDLETON, J. V. D., Major and Surgeon. Ordered to relieve Surgeon B. E. Fryer from duty as post surgeon at Fort Leavenworth, Kan., on or before July 1st. Par. 5, S. O. 183, Headquarters Department of the Missouri, June 28, 1884.

GIBARD, J. B., Captain and Assistant Surgeon. Ordered to relieve Surgeon W. E. Waters from duty as post surgeon at Plattsburg Barracks, Plattsburg, N. Y. Surgeon Waters, upon being relieved, directed to return to his proper station (Madison Barracks, N. Y.). Par. 3, S. O. 181, Headquarters Department of the East, June 30, 1884.

BENHAM, R. B., First Lieutenant and Assistant Surgeon. From Department of Dakota to Department of Texas.

GORGAS, WILLIAM C., First Lieutenant and Assistant Surgeon. From Department of Texas to Department of Dakota. Par. 8, S. O. 150, A. G. O., June 28, 1884.

WALES, PHILIP G., First Lieutenant and Assistant Surgeon. From Old Fort Colville, Washington Territory, to Fort Cœur d'Alene, Idaho. Par. 3, S. O. 89, Headquarters Department of the Columbia, June 23, 1884.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the Navy during the two weeks ending July 5, 1884:*

KNIGHT, J. S., Surgeon. Placed on retired list.

WHITING, R., Passed Assistant Surgeon. Detached from U. S. S. Vermont, and ordered to Marine Rendezvous, New York.

BABIN, H. J., Surgeon. Detached from Marine Rendezvous, New York, and ordered to U. S. S. Minnesota.

WELLS, H. M., Surgeon. Ordered for examination preliminary to promotion.

LUMSDEN, G. P., Passed Assistant Surgeon. Detached from U. S. S. Pensacola, and placed on waiting orders.

WELLS, H. M., Surgeon. Detached from Naval Hospital, Brooklyn, and ordered to U. S. S. Lancaster.

SATRE, J. S. Appointed Assistant Surgeon. Commission dated June 27, 1884.

CORDEIRO, F. J. B. Appointed Assistant Surgeon. Commission dated June 27, 1884.

Society Meetings for the Coming Week:

MONDAY, July 14th: Chicago Medical Society.

TUESDAY, July 15th: American Otological Society (Catskill, N. Y.); Medical Society of the County of Otsego, N. Y. (annual); Ogdensburg, N. Y., Medical Association.

WEDNESDAY, July 16th: American Ophthalmological Society (Catskill, N. Y.—first day); New Jersey Academy of Medicine.

THURSDAY, July 17th: American Ophthalmological Society (second day).

Letters to the Editor.

CELLOIDIN AS AN IMBEDDING MASS.

137 EAST FIFTIETH STREET, NEW YORK, July 5, 1884.

To the Editor of the *New York Medical Journal*:

SIR: I would like to ask, through your journal, what the nature of the objection is, to which Dr. Freeborn alludes in

cautioning those employing celloidin as an imbedding agent, against the use of absolute alcohol and oil of cloves. I have seen sections made in the way Dr. Freeborn describes, and it has seemed to me that they could only have gained in appearance if the celloidin had been removed prior to mounting them. I refer particularly to sections of such organs as the spinal cord, which it is desirable to see the outer contours of, and to recognize the fissures and perivascular spaces in. What is true of the spinal cord must be still more true of eye and embryological preparations. The objection certainly can not rest in the difficulty in mounting on the slide—a difficulty which there are so many devices for overcoming. In asking this question, I desire to take the opportunity of expressing my obligations to the gentlemen who have made what promises to prove an invaluable method early known to us on this side of the Atlantic.

Truly yours,

E. C. SPITZKA.

Proceedings of Societies.

NEW YORK OBSTETRICAL SOCIETY.

A STATED meeting was held February 19, 1884, the President, W. M. POLK, M. D., in the chair.

Dermoid Cyst of the Ovary.—Dr. J. B. HUNTER related the following case, and presented the specimens: The patient was a widow, twenty-eight years of age, who had come to him some weeks before, stating that she had suffered for eight years from severe dysmenorrhœa and metrorrhagia, which had grown worse from year to year. Her periods continued for fourteen or fifteen days. All the usual remedies had been tried in vain. Upon examination, Dr. Hunter found one ovary enlarged and lying behind the uterus. The other ovary could not be felt. A week ago he performed laparotomy, making an incision more than two inches long. The right ovary was found to be enlarged, and was removed; the fimbriated extremity of the Fallopian tube was pretty firmly attached to it. The left ovary was then removed. It was enlarged, and, on cutting into it, about one half its substance was found to consist of a dermoid cyst, containing hair and pultaceous matter. The tubes were also removed with the ovaries. The abdominal wound was closed in the manner which Dr. Hunter had adopted for some time: a silver-wire suture was passed through the abdominal wall and the peritonæum; the edges of the peritoneal surfaces were then carefully coaptated with catgut sutures, and the remainder of the wound was closed with silk sutures. The wound had healed by first intention, and the patient had had no bad symptoms. Dr. Hunter had obtained better results from this method of closing the abdominal wound than from any other.

Dr. C. S. WARD remarked that the specimen was the smallest dermoid cyst of the ovary which he had ever seen. With reference to Tait's operation, he knew of no other surgical operation of equal magnitude which was so uniformly successful, so far as recovery from the operation was concerned.

Dr. CLEMENT CLEVELAND inquired whether there was anything in the anatomical appearances of the structures of the pelvis which would account for the condition of the ovaries and the symptoms.

Dr. HUNTER replied that the uterus was retroverted and one ovary lay behind it. It had been thought that the woman was suffering from cellulitis, but he found no evidence thereof. He thought that, where there was sufficient disease of the ovaries

to interfere with their function, it was common to find aggravated pain. With reference to other methods of closing the abdominal wound in cases of laparotomy, he said that a number of patients were known to return with ventral hernia, or with a weakness of the abdominal walls, which was a source of discomfort to them ever afterward.

Dr. WARD said it was not uncommon for hernia to occur after laparotomy for the removal of a large tumor, but he had never known it to take place after Tait's operation. This might be accounted for, in part, by the fact that Tait's operation had been comparatively recently introduced. He thought, however, that the real explanation was that the tunicity of the abdominal wall still remained, and was in no wise compromised by the operation. He had not had an opportunity to witness Dr. Hunter's method of closing the abdominal wound; it might be an improvement upon other methods. He had, however, had occasion to open the abdominal cavity several times after laparotomy for large tumors, and he had found firm union by adhesion of the peritoneal surfaces within forty-eight hours after the operation. He should think the same thing would occur after Tait's operation.

Dr. HUNTER remarked that he had not seen any case of hernia following Tait's operation, but he had seen very weak abdominal walls, a condition which would favor hernia. He had seen imperfect closure of the peritonæum, favoring abscess in the abdominal wall.

Dr. WARD had seen abscess, but it had been extra-peritoneal, and it usually opened or was incised in the line of the sutures; he had never known a mural abscess burst into the abdominal cavity. The tendency in the peritoneal wound was to union by adhesion, and, if mural abscess occurred, it followed the tracks of the sutures in seeking an outlet.

Dr. HUNTER recalled a case in which a secondary operation was necessary on account of an abscess which had broken into the peritoneal cavity. Abscess was more likely to develop in the cellular tissue than in the cavity.

The PRESIDENT said he once lost a patient after performing Tait's operation from just the condition of which Dr. Ward had spoken. The patient was an unusually stout woman, and the abdominal wall was very thick. Of course, there had been no recent distension of the abdominal cavity, although she had had a child several years before. When he got through the operation, which was easily done, and started to bring the walls together, he discovered that, when he tightened the sutures, they cut directly through the peritonæum, and, after putting in all the sutures save the last one, in running his finger underneath, so as to see what the condition was, he discovered that each suture had cut through the peritonæum, and that the fascia was in direct contact with the intestines. He was so firmly impressed with the importance of bringing the peritonæum together that in that case he unwisely undid the sutures and attempted to get the peritonæum together, but the intra-abdominal pressure was so great that it was an utter impossibility to accomplish it. He had said "unwisely undid the sutures," because he believed that the handling of the cut surface in consequence of his efforts to bring the peritonæum together was the direct cause of the formation of an abscess, which abscess began in the upper portion of the incision, and finally emptied into the peritoneal cavity, causing general peritonitis and death. So that the opinion he held was this: that all experience went to show that it was of the greatest importance to get the peritonæum together, and, in ordinary cases of tumor, where the peritonæum was strong and well stretched out, it could be accomplished without difficulty; but in certain cases, where the condition he alluded to was present, it was not very wise to insist on having everything just as we would like. Of course,

the abscess might have formed in any event, but he was sure he had aided its formation very much by the handling that the cut surface was subjected to.

The President then showed two specimens, from different patients, and related the cases as follows:

Dermoid Cyst of the Ovary.—The patient gave a history of pelvic discomfort, and, upon examination, a tumor of about the size of an orange was found in the region of the right broad ligament, and nothing upon the left side, although all the pain was upon the left side. The uterus was displaced somewhat, on account of the presence of this tumor upon the right side. The patient was not in very good condition for operation, because she had some bronchitis, which had been going on a good while. She had a good deal of cough with it—more than the amount of bronchitis seemed to account for. It was thought there might be a certain reflex element in the production of the cough. At any rate, the pain was so constant and her distress was such that an operation was considered advisable, and it was done last Saturday. The tumor which you see there was found on the right side, and proved to be a dermoid cyst. It was free, and consequently was removed without difficulty. The tube was taken out along with it. The tube on that side, however, was entirely free from any disease, and the fimbriae were distended about as well as can be seen in any specimen. . . . When I searched the other side of the pelvis I found that the tube was dilated, and that the outer end of it, the fimbriated end, had grasped the posterior surface of the ovary and was firmly adherent—so firmly that the outer end of the tube was closed. That was interesting as showing that it was the cause of the pain the patient suffered upon the left side. The tube on the right, as you see here, was free from disease. That on the left explained the difficulty. The ovary was cirrhotic, as we express it, so that I removed it. I used the ether apparatus of Clover in the operation, which, as you know, involves the re-inhalation of the ether over and over again, together with the expired air; so that you use a minimum amount of ether, but its use is always accompanied by more cyanosis than you see with either ether or chloroform administered in the ordinary manner. The result in this case was about as good as in all others in which I have used the instrument. There was no vomiting, and there was very little shock after the operation. The patient was quite blue, however, but the presence of a good deal of mucus in her bronchial tubes probably accounted for that in great measure. Everything went well until Sunday afternoon, about twenty-four hours after the operation, when the temperature suddenly rose to 104° F., and remained at or above that point until yesterday (Monday) afternoon, when it dropped to normal. The sudden rise of temperature I thought was connected in some way with the wound, but, as there was total absence of any local sign or symptom of inflammation there, and the temperature dropped so suddenly, I came to the conclusion it was in all probability due to some morbid condition of the lung, because there were such intense dyspnoea and cyanosis. It was thought she would die; the temperature rose to 106° F., the breathing became very superficial, and she was as blue as we sometimes see children who are born cyanotic. However, her temperature dropped, under the influence of the rubber coil, quinine, and mainly as a result of the subsidence of the inflammatory process, or whatever it may have been. To-day her condition is as good as it could possibly be—the temperature being normal, the pulse a little over 100, and the patient taking nourishment very well. The cyanosis in this case was no doubt intensified by the opium, although the latter was not given in unusual amount (a fluidrachm of Magendie's solution in the course of sixteen hours). The patient died on the fifteenth day after the operation, the cause of death being double

catarrhal pneumonia, having its origin in the chronic bronchitis, and its immediate cause being the action of the ether and the opium.

Myotomy.—The other specimen is a uterus taken from a patient thirteen days ago. This patient had the ordinary history of fibroma of the uterus, with excessive menstrual discharge, which weakened her a good deal. I determined, therefore, to perform Hegar's operation upon her and remove the ovaries and tubes, but I found that she had some albumin in her urine. Before that it had not shown itself, and this made me postpone the operation ten days. Finally, when it disappeared, her condition being good, I opened the abdominal cavity. I planned for the operation finally performed, but it was a plan that I did not intend to follow out unless forced into it. My original design was simply to take out these ovaries and the tubes, and possibly ligate the ovarian artery, if I could get at it easily. I endeavored, before opening the abdominal cavity, to ascertain the condition of the ovaries, but it was an impossibility. I opened the abdominal cavity, and, getting my fingers down, I found the ovary on the left side with no adhesions, but it was very difficult to get it up to the opening. The usual manoeuvre of lifting the uterus by way of the vagina was resorted to, which brought it up—so well up that I got at it without difficulty. I found the ovary in close apposition with the pampiniform plexus, which upon that side was very much enlarged. In ligating the ovary, I attempted to use Mr. Tait's Staffordshire knot, but it slipped after I had cut away the ovary, and the stump, which contained not only the ovarian vessels, but a portion of the pampiniform plexus, was of such size that it was impossible to catch it. I made successive futile efforts to ligate it, but the more I attempted the worse I made it, for every time I tried to put the ligature into tissue I simply imbedded it in the pampiniform plexus, and the vessels opened and blood spurted. Under these circumstances there was nothing left for me to do but to remove the uterus. I therefore enlarged my incision, passed a rubber tube around the cervix, and cut away the body of the organ. I did not use the clamp, but simply left the rubber tube in position, using that as a ligature. I found that, owing to the thickness of the abdominal wall and the presence of a fibroid tumor on the anterior uterine wall (so low that it really encroached upon the internal os), I had difficulty in getting a good stump of sufficient length to be easily brought out of the wound. Still, by introducing pins and lifting it up, and by carefully turning in the peritonæum and stitching it to the stump below the ligature, I managed to get it in proper extra-abdominal position.

The patient has done very well up to to-day. The peritonæum has united firmly, but an abscess developed along the line of the sutures and prevented the proper union of the wall. By fiding the pus and washing it out carefully, however, and putting on adhesive plaster, I have managed to get it together very well. The patient to-night is in good condition, but the slough over the stump (this is the thirteenth day) is still firmly adherent. I take that to be in part due to the fact that I was obliged to include a fibroid tumor in the ligature. The points of interest in the case to me are: the difficulties that I experienced in getting a proper stump, owing to the presence of the fibroid tumor, the thickness of the abdominal wall, the shortness of the pedicle, and then the facts connected with the bleeding from the stump of the ovary owing to the shortness of the attachment of the organ to the posterior portion of the broad ligament in the proximity of the pampiniform plexus. But for this last fact, the patient would simply have been rid of her ovaries and tubes. But then, hæmorrhage occurring, and it being impossible to arrest it, it became absolutely necessary to remove the uterus.

[*Note, June 18th.*—After a sharp attack of peritonitis, the patient made a good recovery.]

Dr. W. T. Lusk inquired as to the exact way in which Dr. Polk applied the elastic ligature.

The President replied that he lifted the uterus out of the abdominal cavity, as there were no adhesions, just as in the Müller modification of Porro's operation, and put the tubing around it while it was thus raised, putting it around double. At first he put the tubing around single, but it broke.

He wished to correct a statement made in the original report: the parietal peritonæum was not in contact with the entire circumference of the stump below the ligature; the two structures were separated by the ligature at the upper side for a space about as large as one's finger-nail. This had induced him to put in a drainage-tube above the stump. The resulting sinus had not closed, and had caused him some anxiety, as, from its position, it had become a receptacle for the oozing from the sloughing stump.

Dr. Lusk said that, when in London, last summer, he saw Dr. Bantock operate in a case in which the tumor was of about the size of that presented by Dr. Polk, and he was very much pleased with the action of the clamp and wire with which he drew out the uterus. The wire was sufficiently strong to guard against any possibility of breaking, and was so stiff that it could not be handled by the fingers, but required a special pair of forceps, which Dr. Bantock had devised for seizing it, turning it round the stump, and attaching it to the clamp.

Dr. HUNTER had operated in a case similar to Dr. Polk's last summer, and in that instance he employed a piece of rubber tubing about as large as that on a Davidson syringe, wrapping it twice around the stump, thus controlling the hæmorrhage perfectly. He then put on the clamp and cut off the entire mass. He reported the case at the time, but had not yet reported the sequela. A little sloughing took place around the stump, and the neck of the uterus came out entire. A fistula led from the abdominal wound down into the vagina, and required to be washed out for about two weeks. The sloughing was probably to be accounted for by a small portion of the vagina having been included in the clamp. The fistula had gradually contracted and closed, and the patient had done well. Examination by the vagina at present showed no remains of the cervix.

The President: I wished to put a clamp on underneath this tube, but I really did not have the room. I was afraid to make greater traction, through fear of lacerating the tissue. So I had to depend upon what the pins would do for me, and they held it up very well.

Dr. HUNTER remarked that in his case it was extremely difficult to raise the uterus high enough, and he was afraid the clamp would cut into the abdominal wall and cause the patient pain, but she did not complain of it in the least.

Dr. WARD said that Hegar's operation, as compared with Tait's, was the more difficult and serious of the two. With reference to removal of the uterus, he thought fashion had guided the profession largely in the use of the elastic ligature. It seemed to him a better method was by the use of the wire éraseur, whereby the mass could be constricted, and by applying the ligature in its track. He believed in the intra-peritoneal method of treating the stump, the same as in ovariectomy. The cases which he had observed did best if the stump was returned. Last summer he witnessed an operation by Dr. W. T. Bull, in which he constricted the uterus by the wire éraseur, and then ligated the stump with a strong silk ligature. There was very little bleeding during the entire operation. After the operation Dr. Bull applied iodoform to the stump thoroughly, and dropped it, and the patient recovered without a bad symptom. It was true that in some cases the wire éraseur would

cut into the nterine tissue if it was very friable; but in other cases it would work very well indeed. He believed that by this method sufficient constriction could be made with the wire to make ligation safe enough to allow of the pedicle being dropped.

(To be concluded.)

Reports on the Progress of Medicine.

MATERIA MEDICA, THERAPEUTICS, AND TOXICOLOGY.

By GASPAR GRISWOLD, M.D.

The Antagonism of Drugs.—Dr. Walter G. Smith ("Dublin Jour. of Med. Sci.," Jan., 1884) begins by defining the term and distinguishing between it and "antidotism." An antidote is a substance which, by chemical action, can deprive another substance of its properties, rendering it inert, or at least insoluble. An antagonist is a substance which produces effects opposite to those of another substance already absorbed. Antidotes act *chemically*, and neutralize the substance; antagonists act *dynamically*, and oppose the effects of the substance on the system. Example of antidote: Sodium sulphate and acetate of lead = lead sulphate (insoluble). Examples of antagonism: Atropine and morphine, chloral and strychnine. The author calls attention to the most famous views on the subject of antagonism, using the case of atropine and pilocarpine as an illustration, as follows: If atropine is injected into a cat, the salivary secretion is arrested at once; the secretion is restored by the injection of pilocarpine. Rossbach explained this on the hypothesis that the pilocarpine acted by stimulating to excessive action the few gland-cells not paralyzed by the small dose of atropine. A more generally accepted view is that of Langley: that the cells are prevented from acting by the atropine, but act again so soon as pilocarpine enough is given to triumph over the atropine. This view he supports by continuing the experiment indefinitely, giving first a small dose of atropine to check secretion, restoring it then by a small dose of pilocarpine, checking it again with more atropine, restoring it again with more pilocarpine, and so on, many times in an hour, as long as the integrity of the tissues permits experiment. This seems to demonstrate that, when two medicines are given whose effects are directly opposed, the organ affected reacts to the medicine which is given in larger dose, and is affected to a degree corresponding with the excess of the large dose over the small one. To illustrate this, if five grains of one medicine exactly antagonize five grains of another, and if seven grains of the one and five grains of the other are given simultaneously, the effect will be the same as if two grains of the former had been given alone. If five grains of each are given simultaneously, the effect is the same as if no medicine had been given. In such a case a true antagonism would exist between the two drugs, their actions summing themselves up algebraically like *plus* and *minus*. It must be admitted that even in the case of such antagonism it is easier to reduce an excessive stimulation down to the normal by a suitable antagonist than to accomplish the converse—i. e., to level up a condition of extreme depression. For example, chloral hydrate is more likely to save life when a fatal dose of strychnine has been given than strychnine is to save life after a fatal dose of chloral hydrate. It must also be admitted that the antagonism of drugs is beset with limitations, the antagonism being sometimes true only for certain doses, or remaining true for certain organs longer than for others. For instance, gr. $\frac{1}{15}$ of atropine helps the action of gr. $\frac{1}{4}$ of morphine, but gr. $\frac{1}{10}$ of atropine counteracts the

effect of gr. $\frac{1}{4}$ of morphine. The antagonism between atropine and morphine persists in the pupil long after doses have been reached in which both act as depressants of respiration. A further difficulty in the matter of antagonism is the fact that too large doses may affect the tissues of the body so that the organs may be paralyzed and the antagonism not demonstrated. For instance, if a very large dose of atropine is given, the salivary glands may be so thoroughly paralyzed that no quantity of pilocarpine will restore their function. At the same time, enough atropine may be given to counteract three and a half times the fatal dose of physostigma (Fraser). The therapeutic importance of clearing up this matter is simply incalculable, and its significance can not be overestimated.

Paraldehyde.—M. Dujardin-Beaunet ("Bull. gén. de thérap.," Jan. 30, 1884) thus describes this new hypnotic: It is a triple condensation of aldehyde (C_2H_4O), and is denoted by the formula $3(C_2H_4O)$, or $C_6H_{12}O_3$. Aldehyde has hypnotic properties, but can not be swallowed on account of irritating vapors which are given off in great quantities when it is taken into the mouth, and produce most distressing choking and lachrymation. Paraldehyde is crystalline, and soluble in ten parts of water; it is entirely free from the disadvantages of aldehyde. The author has employed it largely in the following prescription: R Paraldehyde, 3 ij; alcohol, 3 ij; syr. simp., 3 ij; tr. vanilla, 3 j. M. Sig. One or two tablespoonfuls. All patients agree that it is less unpleasant to take than chloral. Its hypnotic effect is well marked, but it has no anodyne properties whatever. Patients awake from its influence without headache or discomfort of any sort. It has no effect upon the secretions. In cases where there is pain or very intense restlessness, as in uremia, opium or chloral is to be preferred. But, where a simple insomnia is to be treated, paraldehyde meets the requirements better than any drug the author has ever seen. It seems not to have any tendency to depress the heart or the respiratory system, as has been abundantly proved by experiments upon dogs; and the sleep caused by it is so light and natural that a slight pinch causes awakening, even after large doses have been taken. The author has used it in a great number of cases, but not long enough to determine whether there is a tendency to form a habit, as in the case of chloral.

In the same journal, M. Yvon thus describes the substance: Aldehyde is an intermediate substance between alcohol and acetic acid, in the acetous fermentation. Alcohol is C_2H_5O ; this becomes C_2H_4O (aldehyde). Aldehyde (C_2H_4O), when exposed to the air, takes one atom of oxygen and becomes $C_2H_4O_2$ (acetic acid). If three parts of aldehyde are condensed, a new body is formed with distinct properties. This is called paraldehyde $3(C_2H_4O)$, or $C_6H_{12}O_3$. Pure paraldehyde is crystalline. It is soluble in ten parts of water, and has a pungent taste, but less so than that of chloral. It may be prescribed in the following form: R Paraldehyde, 3 j; spir. menth. pip. 3 ij; aqua q. s. ad 3 ij. M. Sig. Tablespoonful dose. The preparation of paraldehyde is not yet general in France, and the only reliable samples must be obtained from the author. He is at present laboring to perfect its manufacture, preparatory to making it an article of commerce.

Bromide of Ethyl as an Anæsthetic.—Mr. W. Roger Williams, of the Middlesex Hospital ("Brit. Med. Jour.," March 1, 1884), strongly recommends the bromide of ethyl to produce primary anesthesia. He makes a cone of a towel with paper between its folds, as is usually done for the administration of ether. One drachm of the bromide of ethyl is poured into the cone, which is then closely applied to the face, excluding air as far as possible. Anæsthesia is complete within sixty seconds, and lasts two minutes. The patient awakes without nausea or headache. The author has used bromide of ethyl to induce this

primary anesthesia in three hundred cases; he never employs it in cases requiring prolonged anesthesia. He quotes Dr. Chisolm's paper in the "Maryland Medical Journal," who recommends the use of bromide of ethyl in such short operations as slitting the canaliculi, passing nasal probes, etc.; also Dr. Prince's, in the "St. Louis Medical Journal," who recommends it as a precursor to sulphuric ether, and prefers it in this relation to nitrous-oxide gas.

The Sodium and the Potassium Bromides and Iodides.—

Dr. T. J. Hudson, in a paper on bromide and iodide of sodium ("Lancet," Dec. 22, 1883), sums up as follows their advantages over the bromide and iodide of potassium: He first calls attention to the tendency of potash to produce anæmia, digestive disturbance, and increased solid urinary constituents; also its depressing influence on the heart. Soda has none of these effects. It relieves dyspepsia, increases the water of the urine without affecting the solids, and has no effect upon the heart. For these reasons there is much less of reactive disturbance after large doses of the bromide of sodium than occurs after similar quantities of bromide of potassium. The potash salt contains relatively more bromine, and the dose of the sodium compound should be larger in the proportion of about fourteen to twelve. In ordinary slight nervousness, and in insomnia and the like, give the bromide of sodium to prevent the after-effects of the potash. In delirium tremens, give the bromide of sodium to avoid the depressing influence of potash on the heart. In cases of epilepsy the bromide of potassium seems to be more efficient, but, where the treatment is kept up for a long time, substitute the bromide of sodium to avoid digestive disturbances and general systemic depression. One hundred grains of the bromide of sodium may be given at a dose for any purpose without danger and without any unpleasant after-effects. Iodide of sodium was tried in syphilis, in large doses, but did not act so rapidly as iodide of potassium; it was, however, efficient, and was often substituted with advantage where patients were suffering from the effects of long-continued iodide of potassium. In aneurysm the iodide of sodium was much less efficient than the iodide of potassium, probably because it lacked the cardiac depressant effects of the latter. In whooping-cough the author found the bromide of potassium more efficient; this he explains by the supposition that the potash depresses the cerebrum.

Sudden Death during Chloroform Anæsthesia.—Dr. F. Junker (*Ibid.*, Jan. 5, 1884) describes a case of death during chloroform narcosis, but not from it, which occurred at Bardeleben's clinic at Berlin. The patient was suffering from a fracture of the upper end of the shaft of the femur. He was put under chloroform with all the precautions, but suddenly became collapsed, and died in spite of all efforts to resuscitate him. During the efforts at resuscitation, Professor Bardeleben expressed doubts as to the death having been caused by chloroform. The post-mortem examination was made in Professor Virchow's pathological laboratory and disclosed the cause of death—fatty embolism of the lungs. The femur was broken at a point where it is especially rich in marrow, and the fat globules from this source had entered the veins in large quantities and had occluded the pulmonary capillaries, thus causing death by preventing the pulmonary circulation.

Ergotin.—Dr. Ringer and Dr. Sainsbury, in a very interesting paper on ergotin ("Brit. Med. Jour.," Jan. 19, 1884), describe some experiments which go to prove that it causes spasm of the arterioles by direct action. A tortoise is taken, the brain and spinal cord are broken up, and the tortoise is cut transversely in two. The continuation of the abdominal aorta is then found on the cut surface of the posterior section and into it is thrust the end of a cannula, through which is supplied, by siphon action, a saline solution 0.6 per cent. The saline solution passes from the

abdominal aorta into the capillaries of the posterior half of the tortoise, and then into the veins. As it escapes from the cut veins it is collected in a vessel and measured. The pressure in the aorta is always the same, the saline solution being supplied by siphon action at a rate free from variation. Any variation, therefore, in the amount of fluid escaping from the severed veins in a given period must be due to changes in the caliber of the arterioles. With a preparation like this the authors performed the following experiment: As soon as the regular rate was determined at which the solution was flowing through the tortoise, some Bonjean's ergotin was added to the solution. Almost immediately the amount of fluid escaping from the cut veins was diminished from one half to two thirds, showing that a contraction of the arterioles had occurred. When a simple solution was substituted, the arterioles gradually relaxed, and the flow returned to its original rate. The use of an ergotized solution again diminished the flow as before. This experiment seems to prove conclusively that ergotin causes the arterioles to contract; and, since the spinal cord had been broken up, the contraction would seem to be due, not to a central influence, but to an effect of ergotin upon the arterioles themselves. This result is important as bearing upon the use of ergotin locally, by injection into the tissue to be affected.

Metallo-Therapy.—Dr. Grace Peckham ("Arch. of Med.," Dec., 1883) advances the following opinions: 1. The metals generally used are iron, zinc, copper, gold, silver, tin, and platinum—especially the first four. The plaques, or discs, should be an inch in diameter, circular (although the shape makes no difference therapeutically, circular plaques are most convenient), and should have a hook or ring on the free surface through which a ribbon may be passed to suspend them. They should be smooth, and their thickness or weight is unimportant. 2. The number used should be generally from five to nine. One has been used alone, and, on the other hand, Burg fairly "draped" some of his patients with discs. The author has generally used nine. 3. The selection of a metal is purely experimental. It is customary to begin with iron, and then to try the others in the order named above. The disc experimented with should be left on for about thirty minutes; if during that time no modification of symptoms has occurred, and no sense of burning or stinging at the site of the disc has been experienced, another metal should be tried. Under an active disc, the skin is frequently reddened, sometimes vesicated, and sometimes it sweats profusely. When a metal has been found which is in accord with the "metallic sensibility" of the individual, nine discs of it should be hung about the part and kept there until disappearance of the symptoms, or at least great amelioration of them, has taken place. They are sometimes allowed to remain for several days, until a cure is effected. Should relapses occur, the discs are to be used again, in the manner which was successful before. 4. Burg regarded the external use of metals as merely a stepping-stone to their internal use. The internal therapeutic action, he states, is always the same as the external, and the latter should be employed to determine the personal idiosyncrasy. The metals are given in the form of powder, finely minced leaves, or in the various salts. It matters little which salt is used. Sometimes mineral waters which contain the desired metal in a definite quantity are used. 5. As regards the affections which have been successfully treated by metallo-therapy, the list includes most of the neuroses, and not a few symptoms caused by organic disease. Anæsthesia, paresis and paralysis, deafness, achromatopsia, and amblyopia are among the *hypo-neuroses*; the *hyper-neuroses* include pain, cramps, spasms, convulsions, etc. Insomnia is one of the affections for which a great deal has been done by metallo-therapy.

Inunction as a Febrifuge.—Dr. P. Colrat, in a very inter-

esting paper on modifications of temperature produced by general inunctions, especially in the febrile diseases of children ("Lyon méd.," Jan. 13, 1884), recalls the celebrated experiment of Fourcault, reported to the Academy of Sciences in 1838, in which he proved that the application of an impermeable varnish to the skin of an animal caused a fall of temperature, instead of causing it to rise, as would naturally be anticipated. Schlemann, of Hannover, was the first to apply the discovery to therapeutics, but limited it to the treatment of scarlatina; he believed that it diminished fever, quieted the patient, prevented complications, and diminished the chances of contagion. The treatment was soon generally adopted, and, although many did not believe that it had any influence in preventing complications, it was on all sides found to lower the temperature and diminish irritability. The author of this paper has employed inunctions in a large number of cases, and has arrived at the conclusion that they are of use in all febrile diseases, and that their use should not be limited to the eruptive fevers. He finds that the temperature begins to fall immediately after an inunction, and continues to fall for about an hour; it then remains stationary for about half an hour longer, when it commences to rise again. At the end of two hours it has reached the point where it stood before the inunction. The temperature again falls when a second or third inunction is performed, and may be kept down indefinitely by repeating them. The younger the child, the more marked the effect; the temperature may fall as much as three or four degrees. General inunctions have been so freely practiced that it is quite evident that they are without danger, and one finds it difficult to explain the famous case of the child who was gilded to personate the "golden age" at the inauguration of Leo X, and who died in consequence. Senator proposes to explain this case as due to poisoning from the solution of gold employed in the gilding. The fall of temperature which follows inunction has been explained by Laskjewitsch and Lomikowski as due to increased loss of warmth by radiation. These experimenters proved that, if a limited portion of skin was covered with grease or varnished, a greater amount of heat was radiated from it than from an equal surface of bare skin. They further showed that, if animals were greased or varnished, they soon died from depression of temperature, the blood in the veins being arterial from non-use of the oxygen contained in it, this last being due to arrest of oxidation and tissue metamorphosis by low temperature. They then prepared other animals in the same way, and showed that they could be kept alive by covering them with cotton wadding, or by putting them in a very warm room, or resorting to any means which prevented the increased loss of body heat which followed the inunction. According to these experimenters, adults are less affected by inunction than children, because they present less surface in comparison with their weight, and are less profoundly affected by measures which increase their rate of heat radiation. Dogs and fur-clad animals die as a result of inunction, because they are naturally prevented by their coat from losing much heat by radiation; when, therefore, the non-conducting properties of their coat are neutralized by the application of ointments or varnish, the loss of warmth is increased so far beyond the normal that life can not continue. The idea that their death under these circumstances is due to asphyxia from suppression of cutaneous respiration is opposed by the fact that the appearances post mortem are not at all those of asphyxia, the blood containing even more oxygen than normal, and even the venous blood being bright red because the cooling tissues did not use the oxygen that was offered them, but allowed it to pass on into the veins, as it does in syncope.

Convallaria and Digitalis.—Professor Coze, assisted by Dr. P. Simon, has completed a series of careful experiments

upon the actions of *Convallaria maialis* and digitalis upon the frog's heart. He finds ("Bull. gén. de thérap.," Dec. 15, 1883) that in both cases a prolonged and strengthened systole is produced after a time, with increased arterial tension and more sustained flow of blood, the diastolic slowing of the blood-current becoming less perceptible under the influence of the medicines. He finds that this increased steadiness of the blood-current is more marked when convallaria is used, although digitalis seems equally able to slow the pulse. In the cases where full doses of digitalis were given, a dangerous tendency seemed to develop for the heart to linger in an unduly prolonged systole, as if it were on the point of stopping altogether. This was not observed when convallaria was used. The author prefers convallaria, on the basis of physiological experiment, as safer and more effective in stimulating the circulation.

Snake-Poison.—Sir Joseph Fayrer, in a very interesting paper ("Lancet," Feb. 16, 1884), first describes the organ which secretes the poison as a compound racemose gland analogous to the parotid. The duct of this gland enters the fang near its root, the fang containing a central canal like the lumen of a hypodermic needle. The gland is so situated that it is compressed between the masseter and external pterygoid muscles when these contract; the result is that several drops of venom are ejaculated from the tiny opening near the point of the fang at the moment when the muscles are contracted in the act of driving in the fang. After several successive bites the supply of venom is temporarily exhausted, and the snake becomes comparatively harmless; in a few hours, however, after the products of the poison-gland have had time to accumulate, the bite again becomes fatal. The activity of the poison differs not only in different species, but also under different conditions of temperature, health, etc. The poison of the rattlesnake, moccasin, and copperhead is neutralized by bromine, iodine, hydrobromic acid (33 per cent.), sodium hydrate, and potassium permanganate (Weir Mitchell). If any of these substances are added to venom, the mixture may be injected without any symptoms resulting. The author says that he has demonstrated in India that snake-venom is absorbed from a mucous surface, contrary to the traditional and almost universal belief. He does not believe that it is safe for any one to suck a snake-bite. The poison is most rapidly fatal to warm-blooded animals, but does kill cold-blooded animals, down to the lowest forms of invertebrate life. Strange to say, poisonous snakes can not poison themselves or other poisonous snakes; innocent snakes, however, are affected at once like other animals. The changes following snake-bite are local and general. *Locally*, the tissues become almost at once the seat of rapid decomposition. Within four or five hours the neighborhood of the bite is found presenting an appearance of ecchymosis over an area of several inches. On section, the tissues are found infiltrated with sero-sanguinolent fluid, containing imperfectly formed, tarry coagula and coffee-grounds granules. Blood does not flow on section. The tissues are in a state of granular disintegration, the capillaries being the first to break down and permit the altered blood to infiltrate the tissues. *Generally*, these blood changes are more or less present, though less conspicuously. Cadaveric rigidity comes on very early. Hematogenous jaundice is frequently present. The poison seems to kill by depressing effects upon the respiratory apparatus. In some cases, where the poison enters a vein, death may be almost instantaneous from paralysis of the heart. The proper treatment is to apply a ligature or pressure on the cardiac side of the bite instantly. A free incision should be made over the bite at once, and any tissue which seems at all discolored or altered should be boldly dissected out. The wound should be washed out with a five-per-cent. solution of potassium permanganate. Warm blankets and alcoholic stimulants are

to be employed as required. In the absence of potassium permanganate, iodine may be used; or any escharotic, such as nitric acid, etc. These escharotics do not destroy the poison, but they convert the surrounding tissues into an impermeable eschar, and thus prevent absorption. The author believes that the blood of those poisoned is itself capable of causing death if inoculated. This would involve the hypothesis that the poison multiplies in the circulation like that of vaccinia, for instance; this view would class snake-venom with zymotic-disease poisons rather than with toxic agents like drugs.

[Some of the author's views are in opposition to those entertained by most other observers; they are as follows: 1. The poison is absorbed by mucous surfaces. 2. Poisonous snakes are not affected by snake-poison. 3. The poison kills by stopping respiration, the heart still continuing to beat. 4. The blood of poisoned animals produces death when inoculated, thus classifying snake-poison as a zymotic poison. He does not speak of the immunity of pigs, which can be bitten by the most venomous snakes without dying; and he does not allude to the antagonistic action of alcoholics when given early and freely. In America, it is well known that life may be saved by the free use of alcohol after a rattlesnake bite, and this has always been considered corroborative of the view that snake-poison acted as a cardiac depressant.]

New Inventions, etc.

A HANDY POCKET EAR-CASE.

DESCRIPTION BY ROBERT BARCLAY, M. D.

DR. SEXTON has devised for physicians who require the aid of instruments for the examination of the ears of their out-patients an aural case which contains, besides the means of illumination of the deeper parts of the organ, instruments for cleansing the external auditory canal of secretions and cerumen, the removal of foreign bodies, and the performance of nearly all operations likely to demand the otologist's or practitioner's attention—such as the incision of abscesses about the ear, furuncles within the canal, and the membrana tympani.

COMPLETE CASE.

It is well always to have everything essential for these purposes kept together in a case, since, when in haste, one is liable to forget something if the instruments are scattered about. Such a collection is shown in the cut of a pocket-case, six and a half by three inches, and one inch in depth, which contains the instruments described below.

CONTENTS OF THE CASE, AND DESCRIPTION OF THE INSTRUMENTS.

1. *Polypus Snare*.—This instrument consists of a handle, cannula, and wire loop. The handle is four inches and a half long, made of ivory, has at one end a receiving cylinder, and on its anterior surface a sliding bar, at one end of which is a milled button by which it is drawn down by the thumb of the hand in which it is held, while at the other end of the bar are three slots or notches into which the wire is passed, the three angular turns thus made securing it more firmly than can be done by winding it around a post, as is required by most snares. The proximal end of the receiving cylinder is beveled on its inner edge to prevent undue friction on the wire. The axis of this cylinder forms an angle of 110° with the long axis of the handle, thus permitting simultaneous vision and manipulation at the extremity of the adjusted por-

FIG. 1.

tion. The wire used is made of malleable iron, No. 35, and the same piece, if readjusted carefully, may be used for two or three operations.

The six instruments to be immediately described below are made to fit the receiving cylinder of the snare-handle for manipulation therewith.

2. *Silver Cannula*.—A part of the polypus snare is made of coin silver; it is $\frac{1}{8}$ inch in diameter.

3. *Myringotome*.—Is lance-shaped, made of steel, and has both edges sharpened.

4. *Sharp-pointed Ear-Knife*. 5. *Probe-pointed Ear-Knife*.—Two small bistoury blades, suitable for any cutting operations in the canal, such as incision of furuncle or abscess.

FIGS. 2, 3, 4, 5, 6, and 7.

6. *Hoe-shaped Scraper*.—This is $\frac{1}{8}$ by $\frac{1}{32}$ inch in surface, with sharp edge, for the removal of granulation tissue from the tympanum and adjacent parts, or the pedicle of a polyp, too small for the use of the snare.

7. *Stout Silver Probe*.—Made rather strong, with large bulb, suitable for probing about polypi and in tympanum; it is less liable than more slender probes to injure the parts or to cause bleeding.

8. *Foreign-Body Forceps*.—This instrument is made to seize an object by a sliding ring which glides down over the blades to their end

when the handle is pressed by the thumb and fingers. Upon the extremity of each blade is *one* needle point, so set that the forceps can

FIG. 8.

take hold of a presenting surface without the exertion of any propulsive force. The two blades, attached to one bar, can rotate in the handle, thus allowing an object, when in the process of removal, to adapt itself to the conformation of the canal. The attachment by *two* needle points provides an axis upon which the foreign body can move from side to side also. With this instrument very strong traction can be made. In cases where the foreign body lies deeply or impacted anywhere within the canal or tympanum, and in removing sequestra, this will prove especially useful.

9. *Small Dressing Forceps*.—Represented in the cut one third of the actual size; it is very light; has smooth, broad ends, which meet with

FIG. 9.

great precision, and whose bite may be strengthened by shortening the grasp upon the instrument. It may be employed as well for removing small foreign bodies lying loosely in the canal, or for small polypi.

10. *Head Mirror and Adjustable Band*.—This mirror is concave, two inches and a half in diameter, about six inches focal distance, and perforated at the center. The head-band is of strong silk ribbon

FIG. 10.

one inch wide, and is held, when adjusted to the head, by a sliding shoe-buckle. The forehead-rest is padded and faced with chamois-skin.

FIG. 11.

11. *Aural Specula*.—These are made of German silver, after the Erhardt [or Gruber] pattern, of three or four different sizes, which fit

one within the other. They may be used as nasal specula at the anterior nares.

12. *Folding Tongue-Depressor, Curette, and Oscope*.—Is made of polished steel, seven inches long when opened, four and three fourths when folded; it is three sixteenths of an inch at its broadest part, and the slender portion terminates in a small curette; has but one angle; is recommended for its lightness, its harmless appearance to young or timid patients, and its sufficient strength for depressing the tongue for ordinary inspection of the pharynx, retracting the lips and buccal walls, and for curetting.

13. *Curved Double Curette*.—Terminates at one end in a plain ring curette, at the other in a toothed, hooked curette. The latter is especially serviceable in cases of foreign body in the canal where syringing proves unavailing, or where the intruder is of such hard or smooth nature that the foreign-body forceps can not secure a hold. In nearly all such cases it can be forced between the object and the walls of the canal, when, from its firm hold—the teeth being set so that, on withdrawal, they become fastened or firmly impinge against the object—effective traction can be made.

FIG. 12.

FIG. 13.

FIG. 14.

FIG. 15.

FIG. 16.

14. *Vulcanite Cotton-Wool Carrier*.—Is five inches and a half long; highly polished except at the tip of the more tapering end, which is left unpolished to insure firmer attachment to cotton-wool twisted about it for wiping out the canal or tympanum. The more abruptly conical, fully polished end permits cotton-wool to be slipped easily off it and left in the canal either as absorbent, tampon, or dilating tent when rolled together very tightly.

15. *Aluminium Cotton-Wool Carrier*.—Is light and delicate, terminating in a sickle-shaped curve; is useful whenever it is desired to make applications to the more remote portions of the cavity of the tympanum, or to cleanse it with cotton-wool brush.

16. *Long Silver Probe*.—Tapering very gradually, six and a half

inches in length, tipped by a very small pyriform bulb; is serviceable in exploring mastoid sinuses especially.

FIG. 17.

17. *Two-Bladed Scalpel*, one of whose blades has a straight back, the other having back and cutting edge of equal curves; both blades secured by a sliding (or spring) catch; can be employed for incising the mastoid region, or for superficial cutting operations on auricle or meatus.

There are compartments in the case intended to contain iron-wire for the polypus snare, cotton-wool, etc.

This case is manufactured by Mr. W. F. Ford, of Messrs. Caswell, Hazard & Co., New York.

Miscellany.

THERAPEUTICAL NOTES.

Inhalations of Nitrogen in Pulmonary Diseases.—Dr. Sieffermann ("Gaz. méd. de Strasbourg"; "Bull. gén. de thérap.") thus describes the effects of these inhalations:

1. With the first inspirations, the patient declares that he can breathe better, dyspnoea diminishes, and at the same time a feeling of well-being supervenes. The pulse becomes small, often thready, from contraction of the radial artery. So long as the process lasts, enfeebled, anæmic, and nervous patients have vertigo, with a sensation of feebleness and of pressure in the head, sometimes deepening into faintness. These symptoms are observed only at the first two or three sittings; the patients have then become accustomed to them and always bear them perfectly well. The symptoms vary in degree with the amount of nitrogen administered.

2. According to Mermagen, the suppression of night-sweats is a constant result, most commonly following the second or third sitting. Other experimenters are not agreed upon this point, some, like Kholschutter, maintaining that the sweats are increased. But Mermagen is very positive, and affirms that it is only in desperate cases of florid phthisis that the sweating is not controlled. He adds that, if Kholschutter's experience differed from this, it is because he used air containing ninety-six per cent. of nitrogen, a mixture almost poisonous.

3. One of the most surprising effects, according to Mermagen, is the very rapid disappearance of the dullness due to tubercular infiltration of the apex, which occasionally takes place after fifteen days of the treatment. Where an infiltration of the apex has been clearly made out, with dullness on percussion, bronchial respiration, and mucous râles, the vesicular murmur is heard again, with small moist râles and a tympanitic resonance. Kholschutter states also that he has seen dullness disappear when it corresponded to chronic infiltrations of the pulmonary parenchyma or to pleuritic exudates. But in several cases he observed the cough become more frequent, and the temperature rise nearly to 104° Fahr. He asserts, indeed, that the temperature rises regularly after each inhalation, which he considers a bad symptom. Mermagen believes that this rise of temperature coincides with the disappearance of the infiltration from the apex, and therefore that it is due to an absorption fever. The two observers' disagreement as to the explanation is probably to be imputed to the fact that one of them used air containing only from two to seven per cent. of nitrogen, while the other employed air impregnated with eleven per cent. of the gas at the least, and sometimes even gave pure nitrogen, so that he often produced poisoning like that due to carbonic acid. By dearly-bought experience, Krüll afterward proved that, to get good results, not more

than seven nor less than two per cent. of nitrogen should be added to the air; so that there is little room for doubt that the effects observed by Kholschutter are to be attributed to the use of excessive doses.

4. All observers agree as to the soporific effects. Mermagen says that he has seen more than one patient go to sleep while the inhalation was in progress, and that others were able to sleep for eight hours at a time, whereas before their night's rest had been prevented by cough and dyspnoea.

5. The appetite is perceptibly increased, and consequently the nutrition improved.

6. A good effect has even been observed upon colliquative diarrhoea, and in patients who were in a desperate stage of the disease.

Irritative cough was certainly ameliorated during the treatment, but the improvement did not continue. The compiler regrets that the breathing capacity was not tested with the spirometer and the pneumotometer, for a comparative table founded on such tests would have furnished the best data as to the results of the treatment.

The Treatment of Scrofulous Bubes.—Dr. Lhuillier ("Thèse de Paris"; "Bull. gén. de thérap.") treats of a variety of inguinal bubo which occurs in scrofulous persons between eighteen and thirty-eight years of age, and appears to result most frequently from excesses in walking or in venery, which cause engorgement of the inguinal glands and favor the localization of scrofulous disease in them, often quite independently of any other scrofulous manifestation. Syphilis also favors the occurrence, and it is then termed syphilo-strumous adenitis (*adénite syphilo-strumense*). Strumous adenitis calls for a general anti-scrofulous treatment, such as cod-liver oil, phosphate of lime, wine of cinchona, and especially preparations of iodine in small doses extending over a long period. During the stage of induration, local treatment is apt to prove fruitless, although applications of tincture of iodine may do a little good; when fluctuation is evident, however, there should be no hesitation, but the abscess must be opened freely, antiseptically, and with Paquelin's cautery if practicable, and an effort made to destroy the wall. If the patient declines to submit to the latter procedure, the cavity may be dressed with tincture of iodine or with iodoform. In the syphilo-strumous form the treatment is the same, but softening may be hastened by the use of mercurial plasters.

Sulphide of Calcium to prevent Suppuration in Small-pox and Chicken-pox.—Surgeon-Major C. J. Peters, of the British army in India ("Indian Med. Gaz."), relates a number of cases in which he succeeded in preventing the suppuration of the cutaneous lesions, and therefore the secondary fever, of small-pox, some years ago, by the local use of a mixture of the pentasulphide and the hyposulphite of calcium (commonly called sulphide of calcium) prepared by boiling a quarter of a pound of quicklime and half a pound of sulphur in five imperial pints of water until the liquid was reduced to three pints in measurement, when it was filtered and kept in glass-stoppered bottles. If ordinary well or river water is used, a white precipitate is liable to form in three or four days, while the solution loses its color and is no longer efficacious; it should therefore be freshly prepared, in quantities only sufficient for three or four days' use. It is applied to the affected parts two or three times a day, with a feather, taking care that none of it gets into the eyes. As a rule, the pocks thus treated did not suppurate, but withered in the course of three or four days. The author believes that the lotion acts by destroying the germs of the disease, preventing suppuration, and guarding against the complications that result from blood-poisoning. He would now combine its use with the internal employment of the drug.

Tannate of Cannabine as a Hypnotic.—Pasinelli ("Berliner klin. Wochenschr.," "Deutsche Med.-Zeitung") has lately been testing the properties of this preparation, recommended some time ago by Frommüller as the best one for producing the hypnotic effects of Indian hemp without the unpleasant collateral effects of the drug. He has given it sixty-three times, in various sorts of cases, in doses of from a grain and a half to seven grains and a half, in the form of powder. In rather more than half the cases the result was satisfactory, deep and prolonged sleep being produced promptly; but in the other cases the effect was either insufficient or nil. He concludes, therefore, that, while the tannate of cannabine is entitled to be ranked with the hypnotics, it can by no means take the place of the others.

EPHEMERAL HIGH TEMPERATURES
IN YOUNG CHILDREN.*

By HENRY N. READ, M. D., BROOKLYN,

ASSISTANT PHYSICIAN TO THE LONG ISLAND COLLEGE HOSPITAL; ATTENDING
PHYSICIAN TO THE SHELTERING ARMS NURSERY.

BOUCHUR, in his admirable work on the "Diseases of Children," has formulated much of his experience in pædiatrics in the shape of aphorisms, many of which bear evidences of his sagacity and the keenness of his powers of observation as a clinician. The one which I shall quote here bears directly on a class of disorders in children in which the cases which I shall present to-night occur. The aphorism is so well expressed, and is so in accordance with the facts, that it deserves to be studied by all who prescribe for children or are interested in their diseases. It is as follows: "In the first stage of childhood there is *no relation between the intensity of the symptoms and the extent of the material lesions.*" The most intense fever, restlessness, cries, spasmodic movements, and convulsions may disappear in twenty-four hours without leaving any traces. These cases are familiar to all practitioners, and have caused many agreeable surprises at their termination; they may, indeed, be said to have induced an amount of "hedging" in the prognosis of children's diseases unknown in the diseases of adult life, and are peculiarly the province in which the powers of homœopathy shine. To attempt to go over the whole ground indicated in this aphorism would be far too tedious a task for me to undertake this evening, and I shall content myself with presenting to your notice one class of these disorders only, which is to me the most interesting of these cases of violent general disturbance which subside so quickly without leaving any results. These are the cases of *ephemeral high temperatures* in infants. I present here six cases, which I have seen recently. These cases are taken at random, and have nothing unusual about them; their features are no doubt familiar to the members of the Society. They are presented with a suggestion as to their possible cause, and to elicit discussion.

CASE I.—The first case was that of an infant under nine months of age. I was called to see the child—a female—about midday, and was told that she had not been sick since her birth till the date of my visit. The mother said the child had been rather fretful during the night, but had nursed during the early morning, and had gone to sleep as usual. About 10 o'clock A. M.—I saw it between 12 M. and 1 P. M.—she noticed that it was sick. It vomited and cried, grew feverish and steadily worse, till she sent for me. I found the patient presenting only the general symptoms of fever, except that the bowels had moved twice and naturally, and it had urinated freely, the urine on the napkin being normal, so far as could be judged, in quantity and color. The pulse was 200 a minute, respiration 80, and the thermometer in the rectum marked 105.5° F. Considerable nervous disorder was present, and, fearing convulsions, a warm mustard-bath was ordered, and four grains of chloral hydrate,

dissolved in a little sweetened water, were administered. The child's skin, I should state here, though hot and burning to the touch, did not present the other characteristics of a feverish skin, but was most resilient and elastic. As the patient grew quiet, I left, but saw her again that evening. Two more doses of chloral—in all, twelve grains—had been given meanwhile. She had been sleeping during the afternoon and was better, and, on visiting the child in the morning, I found her quite well, with a normal temperature, though she had apparently lost some flesh.

The other cases I shall not relate in detail. They presented, in the main, the features that the one described did.

In Case II the patient had a temperature of 108°, and was well in twenty hours.

In Case III there was a temperature of 103.5°, and the patient was well in less than fourteen hours.

In Case IV the temperature was 106°, and there was so much disturbance of the nervous system, with tension of the fontanelles, that I administered chloroform by inhalation, which was followed by a profound sleep of several hours, and a drop to normal temperature within twenty-four hours.

Cases V and VI did not differ in any particulars from those mentioned.

These cases are extremely puzzling—sometimes they are of shorter duration than those given—a sudden jump of the temperature up, to be followed in a few hours by as sudden a fall almost, and subsidence of all grave symptoms. The only explanation which occurs to me of these phenomena is that of the *insufficient regulating power* of the nervous system. The undeveloped state of the nervous system in the young and the troubles it gives rise to are well understood; but the exact influence of the nervous system upon the production of heat within the body is not yet thoroughly elucidated. That it has an important part to play is undoubted. The three factors in the maintenance of the bodily heat at normal temperatures are the metabolism of the tissues, the radiation or conduction of the produced heat, and the regulation of these two processes by the nervous system; and upon the nice adjustment of these forces depends the ability of the animal organism to maintain a steady temperature throughout years of change. Pfüger and his pupils have demonstrated (Foster's "Physiology," chap. v, p. 481) that in warm-blooded animals metabolism is increased by exposure to external cold, in order for them to maintain their normal temperature, the consumption of oxygen and the production of carbonic acid being markedly augmented, whereas in the cold-blooded animals the oxidation of tissue is decreased by cold and increased by heat. And, furthermore, it has been shown that the mechanism regulating these processes is of a nervous nature, since warm-blooded animals in which the action of the nervous system has been suspended by woorara poisoning, section of the medulla oblongata, or otherwise, behave like cold-blooded animals toward heat and cold, their metabolism being increased by the former and diminished by the latter. Although these experiments have been chiefly directed toward the thermotaxic nervous mechanism by which external cold is made to increase tissue oxidation, it may fairly be inferred that a complementary mechanism exists by which metabolism may

* Read before the Medical Society of the County of Kings, June 17, 1884.

be diminished likewise. "And this suggests that pyrexia, or fever, is the result of a paralysis or suspension of this mechanism, the metabolism of the body running riot, so to speak, in the absence of directive and restraining nervous influence" (Foster's "Physiology," p. 485).

A slight glance at the different varieties of pyrexia may also serve to throw some light on our point. In ordinary fever, either symptomatic or specific, we have studied out many of the concomitants and many of the results, in the shape of waste tissue, deficient secretions, etc., etc. In the usual fever cases we have always diminished secretions with increase of oxidation, with or without interference with radiation. If this latter be diminished as metabolic change increases, we have the steadily ascending type of fever—gradual morning and evening increase. But the sudden enormous rise of temperature to what is regarded as an almost fatal, or at least exceedingly dangerous, point, is seen in the adult in lesions of the nervous system only, or in insolation, which may be regarded as a cerebral affection, the highest recorded temperature in Holmes's "Surgery" and Reynolds's "System of Medicine" being in a case of traumatic tetanus, in which the thermometer marked 110°. The highest recorded temperature with which I am acquainted occurred in a case of injury to the spine, the account of which was published in the "Lancet" in the winter of 1880-'81, in which the thermometer reached the extreme height of 112°. This patient recovered, and indeed it may be stated in general that the prognosis is more favorable in cases of high temperature from nervous disorder than in those of increased metabolism with decreased radiation.

The analogy between these cases in adults and the ephemeral high temperatures of infants is marked. The points in favor of the sudden high temperatures in children, followed by as rapid subsidence, being due to disturbed nerve inhibition and not to interference with the other processes, are, briefly, non-interference with the secretions proportionate to the fever, the bowels, urine, etc., being generally, though not always, not very much checked; the skin more moist and natural than in ordinary fever; marked disturbance of the nervous system; lastly, the ready subsidence of the high temperature on the exhibition of a nerve sedative, chloral being the remedy to administer. The warm bath is an excellent adjuvant, but the administration of quinine, digitalis, veratrum viride, or aconite, is more apt to complicate matters than to simplify them. It would be interesting to know whether the increase in urea obtains in these cases as largely as in ordinary pyrexia. Reasoning from the foregoing remarks, it would not be so supposed. Judging from clinical appearances only, the urine is not much altered in quantity, color, and smell. The specific gravity is increased, and in one case in four or five I have found albumin. There is doubtless loss of body-weight; of this I am satisfied, though I have never verified it by actually weighing the patient before and after the attack. The loss in weight will probably be accounted for in the large quantities of carbonic acid excreted by the pulmonary organs, the respirations being greatly increased in number, running all the way from sixty to one hundred in a minute. I had adopted the chloral

treatment of these ephemeral fevers of children from my own clinical experience and observation, but I find the same remedy recommended in these cases by Da Costa and Wilson, of Philadelphia.

The following points may be taken into consideration in endeavoring to make a diagnosis between these ephemeral fevers and others of a specific or symptomatic nature: 1. The absence of any local inflammation, or of the history of any recent injury. 2. The abrupt beginning, without prodromes; the rapid rise in temperature; the early severity of the febrile symptoms, commonly greater at the commencement than in either enteric or typhus fever. 3. The duration is very short, usually not more than twenty-four hours—oftener less than more. 4. Absence of eruption. 5. Absence of the abdominal symptoms of enteric fever and the circulatory symptoms of meningitis. 6. Absence of jaundice, or of the enlargement of the spleen and liver which marks malarial and relapsing fevers. 7. Absence of epidemics of all kinds. (Wilson, "Continued Fevers.")

INDIGESTION AND INTESTINAL CATARRH IN INFANTS.*

By E. H. BARTLEY, M. D., BROOKLYN,

ASSISTANT TO THE CHAIR OF DISEASES OF CHILDREN, LONG ISLAND COLLEGE HOSPITAL.

INDIGESTION and the various forms of diarrhoea in early life are so common in the summer months, especially in the large cities, that the term "summer complaint" is a terror to every mother. Diarrhoeal troubles of infancy are certainly very disastrous in hot weather, with the best treatment we can command.

The object of this paper is not so much to bring forward anything especially new upon the subject as to offer some brief suggestions which may serve as a stimulus for discussion.

At the outset, we must remember that we are dealing with a delicate and only partially developed organism, and not a full-grown man. In the administration of remedies and the selection of nourishment we must use the greatest care not to do harm instead of good.

We can not properly understand or treat any of the diseases of infants until we consider the peculiarities of their organization. We must remember the feeble powers of endurance, the susceptible and ever-varying nervous system, the partially developed digestive organs, and the character of the natural food and digestion of the infant. We should not forget the close relationship of the nervous system and secretion, elimination, digestion, bodily heat, etc.

The effect of the emotions upon the digestion of adults is well known; but the changes from joy to sorrow, fear, anger, or mirth in the infant are wonderfully rapid and great. Fright is not unfrequently followed by an attack of vomiting and diarrhoea, and yet it is almost a universal custom of mothers to put the child to the breast immediately after such a cause for a little unavoidable noise, although

* Read before the Medical Society of the County of Kings, June 17, 1884.

she herself would not think of eating under similar circumstances.

I have known a watery diarrhœa of unusual severity, and leading to a fatal termination, produced by a fall from a baby-carriage.

In another case, a fright caused by a dog running into the house and barking at a child was immediately followed by vomiting and diarrhœa, lasting for three weeks in spite of treatment, and terminating in paralysis of all four extremities, the upper, however, recovering after a fortnight.

We may have a diarrhœa in children from shock or of nervous origin. The danger of intrusting children to careless nurses in regard to intestinal troubles is apparent.

A second variety, closely related to the foregoing, is the diarrhœa of dentition, which Bouchut regards as a nervous diarrhœa.

A third causative agent in the production of diarrhœa in infants is the debilitating influences of miasms, polluted air, excessive heat, and sudden changes of temperature.

Any or all of these agencies may so depress the vital powers as to greatly hinder normal digestion and set up at first indigestion, and then diarrhœa, which is usually very stubborn and likely to assume the choleraic form.

Catarrh of the stomach and bowels is oftener associated with the exhibition of food than with any other cause; it may be either faulty in quantity or quality.

A condition of mild catarrh of the stomach or intestinal tract, in some portion of its length, usually precedes the severer forms of diarrhœa, and I think this is especially the case when the cause lies in the food.

When the food is administered in too great quantities, too much at a time, or too often in reasonable quantities, the effect is to put more food into the stomach than the feeble powers of the child can digest. The excess acts like a foreign body; if not rejected from the stomach by vomiting, it is passed into the intestines and there sets up more or less irritation, producing an excessive secretion of intestinal mucus and digestive fluids in an attempt to get rid of it. The peristaltic movements are increased, and an *irritative diarrhœa* is the result.

The irritation, extending to so large a portion of the intestinal canal, soon depresses the vital powers and, if not relieved, soon induces some graver nervous disturbances, or an inflammatory condition of the mucous membrane, and an attack of watery diarrhœa mixed with undigested food. The result is the same whether the food is taken at too short intervals or in too great quantity at one time. The same result may also be brought about by the exhibition of improper food.

Where mother's milk has failed, and an attempt is made to feed the child upon some substitute, either through ignorance or thoughtlessness, food is selected which the undeveloped organs of the child can not digest, and the same train of troubles is produced.

The one thing which more than any other is the cause of so much trouble is starch in its various forms. Although a few children may be found who seem to have the power of digesting starchy food, the great majority fail to do so to

any considerable extent previous to the seventh or eighth month.

When starchy food is administered in any quantity to young infants in hot weather, it is sure to remain undigested and, acting as an irritant, set up a condition of catarrh. Many children, who seem to thrive upon such a diet during the cool months, begin to fail as soon as warm weather comes.

The irritation of the constant presence of undigested food in the alimentary canal soon produces a state of chronic catarrh, with an excessive production of a tenacious mucus and exfoliated epithelium, and a modified or deficient secretion of the normal digestive fluids. This condition of affairs prevents the proper digestion of even the proper kind of food, and so increases the trouble.

Obviously, it is not wise to give remedies intended to check a slight diarrhœa under such circumstances, but rather remove the offending materials, and then give remedies to assist the digestive juices and restore the tone of the organs. Pepsin, nux vomica, bitter tonics, and mineral acids, with a little mild laxative each day, will be found most useful.

Another feature must be considered in this connection, which tends to keep up a trouble once begun, viz., the fermentation of the digested and undigested food, and of the mucus.

On opening the intestine in fatal cases of catarrh, the mucous membrane will be found coated over with this thick, tenacious mucus, which must interfere more or less with absorption of the digested food. Various secondary or pathological fermentations take place in this easily decomposable mixture of mucus, peptones, sugar, etc. The principal ones are lactic, butyric, and putrefactive fermentations—all caused by the growth of microscopic organisms of the bacteria family.

These organized ferments continually find ingress to the stomach and intestines, in a state of health as well as ill-health, with the food, but it is only when the canal contains an abundance of mucus, unabsorbed or undigested food, or when a quantity of the ferment itself is introduced with the food, as in sour milk, that their growth is so rapid as to cause trouble. The best conditions for the growth of these ferments, aside from the pabulum, are a temperature of from 95° to 105° F., absence or scarcity of oxygen, and a neutral or alkaline medium. All these conditions obtain in the intestines, and it is there that they grow most readily; the lactic ferment, however, can also grow in the stomach when the acidity is not very great, and it usually precedes the butyric.

The substances which most easily undergo lactic and butyric fermentations are the sugars, organic acids (malic, tartaric, citric, and mucic acids), mucus, and soluble albuminoid matters.

The products of the fermentation are lactic, acetic, and butyric acids, carbon dioxide, and free hydrogen.

The acids act to neutralize the alkaline juices of the intestine, decompose the already saponified fats, setting free fatty acids—oleic, palmitic, and stearic—and thus hinder the absorption of fats, which appear in the stools along with undissolved proteids and the fatty acids above mentioned.

The stools usually have a pronounced acid reaction to test-paper, and are mixed with a green substance, the nature of which is still a matter of dispute; but it is probably produced by the action of the acids upon the bile.

The gases above mentioned distend the bowel and give rise to colicky pains.

These strongly acid stools frequently show their irritating properties even upon the skin around the anus and genitals, producing a troublesome erythema.

These ferments are usually introduced with the food, a meal of sour milk containing lactic ferment often giving an overwhelming impetus to the process, and so disturbing the digestion of the infant that days, or even weeks, are necessary to correct it.

Besides these three forms of ferment, another, of an entirely different nature, should be mentioned, which frequently makes its appearance upon the tongue in the affection known as "thrush," or "sprue"—viz.: the *Saccharomyces albicans*, or *Oidium albicans*, closely allied to yeast ferment in appearance and growth. It is well known that this affection, which in itself is trivial, may cause a catarrhal state of both the stomach—probably by exciting lactic fermentation—and the whole intestinal tract. The nurse expresses it by saying that "the sprue has gone through the child."

The child becomes fretful, feverish, and debilitated. This is apt to be followed by green and "curdy" stools, colicky pains, and diarrhoea.

Some mild antiseptic wash—such as potassic chlorate, borax, and especially boro-glyceride dissolved in glycerin—will be found of most service in the local trouble. I usually give one or two laxative doses of olive-oil or castor-oil daily at the same time. Keep the mouth clean, as well as everything that goes into it. See to it that it gets no sour milk. Sarcinic, alcoholic, and acetic fermentations are not much to be feared.

Still another form of fermentation is to be recognized, known as the putrefactive fermentation. This takes place principally in proteid matters, breaking them up into fats, tyrosin and leucin, ammonia, sulphureted hydrogen, carbon dioxide, hydrogen, and nitrogen. These gases are troublesome in causing flatus and colicky pains. This form of fermentation is most active when indigestion is accompanied with constipation, or in the more chronic forms of catarrh without profuse diarrhoea. It is evident that, at the beginning of an attack of indigestion caused by a meal of sour milk, starch, or any other indigestible food, if an unirritating laxative is given in sufficient quantity to empty the bowel, no serious trouble may be expected. But if, on the other hand, considerable time is allowed for the development of these ferments and the other accompanying changes, a few doses of bismuth and opium will not correct the trouble. It will frequently be found that such a condition as eight or ten small stools, composed of white, curdy-looking lumps mixed with green tenacious mucus, and sometimes accompanied by some watery discharge, will persist in spite of all ordinary remedies, for weeks.

In such cases astringents do little or no good, and opium is often worse than useless, it is actually harmful, while a few

doses of benzoate of ammonium or salicin will be of great service.

In the majority of the cases such as I have been describing, the seat of the trouble is in the small intestines.

In order to treat successfully the ordinary cases of diarrhoea and indigestion in infants, then, we must inquire into the etiology, the state of the nervous system, the quality, quantity, and method of giving the food, whether the trouble as it now exists is due to failure of the stomach to digest, or an interference with intestinal digestion by acid fermentations, to miasms, or air polluted with decomposing garbage, or the result of the combined effect of impure air, excessive heat, and improper food. The treatment must be directed to the cause and not entirely to the result. The treatment is always of two kinds—viz.: hygienic and medicinal. In many cases of indigestion, with not too severe a diarrhoea, proper dietetic and hygienic treatment is all that is necessary, and even some of the severer cases, as Biedert has shown, may be successfully treated in this way. The subject of artificial feeding of infants does not properly come within the scope of my paper, but some reference to faulty methods, as causing intestinal disorders, must be made. Here we come upon ground of dispute, bad theorizing, and worse practice.

Opinions as well as practice vary greatly in the dietetic treatment of children. The principal causes for this difference of opinion which may be based upon experience are: 1. Differences in climatic influences; in the state of the weather at the time. A favorable turn of the weather may make a series of successful cases where an excessively hot and sultry day would have proved disastrous to all. 2. Differences in hygienic surroundings. 3. Differences in general vigor of the children affected, due to their station in life. 4. Individual differences in constitution, vigor, development, etc.

The following are a few brief statements which may be found useful in the feeding of infants:

1. The best food for young infants is average mother's milk.

2. The most available substitute for mother's milk is cow's milk, so diluted and modified as to suit the digestive powers of the infant.

3. Chemical analysis of the food alone is not always a safe guide as to the digestibility of any given artificial food—i. e., it is not enough that the analysis shall show the proper proportion of albuminoids, fats, sugar, salts, etc. The question of the easy digestibility of these ingredients must also be considered.

4. Over-feeding is a very harmful practice, and must be prevented.

5. The hygienic surroundings and the development of the infant will in a measure determine the character of its food. A backward, undersized, rachitic or tubercular child in a tenement-house will require more care in feeding than a healthy child in an airy dwelling. This is a fact often overlooked by physicians as well as by mothers.

6. Greater care must be exercised in the feeding of infants during the hot than in the cool months, and foods containing much starch should be avoided.

How shall we get rid of the green, curdy-looking stools? 1. Prevent hard curds by diluting the milk with some bland, unirritating or mucilaginous substance, such as barley-water, or, much better, gum arabic, albumen, or gelatin-water. This seems to prevent a tough, hard coagulum from forming in the stomach, and allows of more perfect digestion of the casein. Barley-water has not been so successful in my hands as I could wish, although I have seen it do good in some cases.

The addition of starch and bodies containing starch I entirely prohibit in children under a year old. And here let me say that some children are as fully developed at nine months as others at eighteen, and must be treated accordingly.

Starch may be used as a diluent if it is previously boiled and liquefied by malt or pancreatic extract, but I much prefer either gelatin or gum arabic, because these substances, when mixed in solution with the milk and then coagulated by dilute acid, are carried down with the casein in a much less tenacious mass, or are not precipitated at all in some cases, but behave like mother's milk. My direction to the mother is usually to make the solution of gum arabic or gelatin by adding a teaspoonful of the clear gum to a teacupful of warm water, and then to add this to the milk in the desired proportion, say 1 to 2 or 3 of milk. I have seen two patients do well and recover in the heat of July by simply letting them suck sticks of gum made by the confectioner of pure gum arabic. If the child is at the breast, I give the above-mentioned diluent, immediately before nursing, in three- or four-teaspoonful doses.

There is one point which I would urge as very important in all cases of indigestion in infants where we find great greediness for food: that they be allowed to feed only once in about three or four hours. A little cool water may be given in the intervals if the child seems thirsty. This greediness in children is always pathological, and must not be indulged; and it will be well if the nurse obeys your orders in this regard. I insist upon this point. In cases of entero-colitis with free watery discharges I have learned that great benefit will be derived by freely administering cool water. I have also found it an excellent plan to exclude milk from the diet for a day or two in those sudden choleraic cases with tendency to collapse, and to give raw meat-juice with a little salt and brandy instead.

The meat-juice may be given very freely, and it is seldom rejected. After the expiration of about forty-eight hours, and after recovery has begun, there is nothing better than milk partly or wholly pancreatized. This measure should not be neglected in severe cases, or where the powers of digestion seem to have become very feeble. In the main I prefer good fresh milk to condensed milk, although this is a matter of experience; some patients will do better on condensed milk, while others will do better on diluted fresh milk. The more I see of digestive troubles in hand-fed babies the more I am convinced that the proper feeding of any particular infant is a matter of experiment and not one of rule. Of course, we can lay down rules which will apply to a large majority of cases, but some cases will be met with which defy all rule. Pure and cool air are of the

first importance, and a change of air is almost always beneficial.

Medicinal Treatment.—In regard to the administering of remedies to children, I would remark that it is advisable not to give powders, but suspend the powder in a liquid, so that you can be sure of the dose given.

Astringents in the early stages of gastro-intestinal catarrhs are uncalled for, and generally injurious.

Opium before the stage of inflammation I rarely give, except an occasional dose of paregoric to secure rest.

In *irritative diarrhoea* the following paste will be found very useful:

R Ol. ricini,	f 3 iv;
Bismuth. subnitratiss,	3 ij;
Magnes. carbonatis,	3 j;
Sacchari,	3 ij;
Ol. anisi vel ol. menth. pip.,	℥vj.

M. Sig. 3 j for a child of six months to one year.

Or we may use:

R Vin. pepsini,	f 3 jss.;
Bismuth. subnit.,	3 ij;
Glycerini,	3 iv.

M. Sig. 3 j at a dose.

When inflammatory diarrhoea has begun, it is well to give a dose of castor-oil to begin with, unless it is certain that no irritating substances or undigested food remain in the canal. This is then to be followed by the usual remedies, including some form of opium. I usually prefer Dover's powder for children over ten months, and the deodorized tincture for those under that age. In cases where there is a great deal of fermentation, or where the trouble can be traced to sour milk, where the stools are very acid and the breath has a sour smell, the best remedy is benzoate of ammonium or of sodium, boro-glyceride, calomel and chalk, salicin, or salicylate of sodium. This last remedy I regard as rather too irritating for general use.

An alkaline watery discharge is always serious, and demands prompt attention. Stimulants will be found necessary in these cases, and the treatment must be with opium, the mineral acids, and astringents. Instead of giving alkalies in these cases, the mineral acids, nitric or aromatic sulphuric, with opium and astringents, will be found most useful. I should advise, therefore, testing the reaction of the discharges in all cases of watery diarrhoea. I have more than once seen a marked change for the better a few hours after a change from the alkaline to acid solutions. The acid, with the vegetable astringents, checks the discharge, lends tone to the capillaries, and stimulates the mucous membrane to a healthier action. Where the seat of the trouble seems to be in the colon, opium, quinine, subnitrate of bismuth by the mouth and by injections, and alcohol are to be recommended.

The opium may be pushed to the extreme of toleration in colitis, but should be used with caution where the trouble is higher up.

For the pyrexia in these disorders I use frequent cold-water spongings, unless the extremities are cold; in this case the warm bath is more beneficial. In the more chronic

forms, following the acute attacks, benzoate of sodium or of ammonium, acetate of lead, and solution of nitrate of iron are to be preferred.

In the purely nervous diarrhœas, bromide of potassium or chloral hydrate will be more beneficial than any other treatment.

A CASE OF DERMATITIS HERPETIFORMIS (BULLOSA).

By LOUIS A. DUHRING, M. D.,

PROFESSOR OF SKIN DISEASES IN THE UNIVERSITY OF PENNSYLVANIA.

ON February 3, 1879, the patient, the notes of whose case are about to be given, was sent to me by Dr. H. G. M. Kollock, of Newark, Del., who in his letter stated that the disease was regarded as pemphigus. The man had been under treatment for some months, during which period he had taken quinine, iron, and arsenic, and had used varied remedies locally, all without relief. Dr. Kollock's letter states: "He has not had a full crop of bullæ for about two weeks, prior to which they would appear in great numbers every two or three days. He has never been entirely free from them."

The patient, Newton B. E. by name, was admitted to the University Hospital, at which date the following record was made: He is sixty years of age, tall and slender, somewhat emaciated, debilitated, and nervous; he is a native of Delaware, a shoemaker by occupation, and is married. There is no special family history. He never suffered any disease of the skin, except occasional attacks of inflammation from poisoning, until eight months ago, when the present disease appeared. He was at the time in average health, and could attribute the outbreak to no cause. It began about the ankles and feet with swelling, heat, and violent itching; the following day eruption manifested itself on the arms and around the neck, and later on the trunk. Several household remedies were applied, but the disease spread until at the end of a week he was well covered with a mixed eruption consisting of papules, vesicles, and blebs, the latter predominating, and some being as large as a walnut. Upon bursting or being ruptured, the walls adhered to the skin and formed crusts. Successive crops of blebs continued to appear until a fortnight ago—in all, during a period of eight months. He has lost flesh, as much, he thinks, as fifty pounds. A new outbreak of eruption is now manifesting itself.

Present Condition.—The disease of the skin is almost universal, involving the greater part of the general surface from the scalp to the soles of the feet. It is made up of variously sized and shaped *vesicles*, *blebs*, and *pustules*, in all stages of evolution.

The vesicles predominate and vary in size from a pin-head to a pea, the majority being as large as small peas. They are notable for their irregularity of shape, being for the most part very irregular, and in many instances angular in outline. Some are raised to the height of a line, others are flat. They are distended and have a glistening, glazed look, and, as a rule, are not surrounded by any areola, rising abruptly from the surrounding healthy skin. They are yellowish and contain serous contents, as in the case of the early stage of herpes zoster.

The blebs, some raised, others inclining to flatten, are met with here and there on the neck, arms, thorax, abdomen, thighs, legs, feet, and hands. Some are as large as a pigeon's egg. They are manifestly advanced stages of the vesicles, or at least often grow from these lesions. They are as a rule tensely dis-

tended and have clear contents; some show cloudy contents and are flaccid. They do not rupture spontaneously. Their contents are alkaline.

The pustules are present in like manner here and there, distributed over the same regions. They are distinctly pustular, having *whitish* contents and more or less inflammatory areolæ; are small, raised, irregular in outline, though less so than in the case of the vesicles, and have a "puckered" or "drawn up" appearance. Excoriations and blood-crusts are conspicuous, and are plainly the result of prolonged scratching. Yellowish, brownish, "dirty-looking" patches of pigmentation, giving the skin the appearance of chronic pediculosis corporis, are also prominent symptoms. *The itching and burning are most distressing.* They interfere with sleep at night. New lesions in great numbers are beginning to form. Some of the earliest are flat *papulo-vesicles*. They can be felt with the finger as small circumscribed infiltrations even before they become visible. In some localities there is a marked tendency for all the lesions to group, two, three, or four being crowded together into a cluster; in other places they are disseminated. Here and there *blebs* are surrounded concentrically by a variable number of small, flat, whitish pustules of the size of pin-heads, making a striking combination.

February 7th.—During the last three days lesions of all kinds have appeared, accompanied by intense itching and burning. Some of the blebs have attained the size of walnuts. On the forehead an abundant crop of variously sized and shaped herpetic vesicles are present.

28th.—A fortnight ago the attack was at its height, vesicles, blebs, and pustules, as well as intermediate forms, existing in profusion. Almost the whole integument was invaded, scarcely a square inch being exempt. The blebs frequently reached the size of a hen's egg; the pustules flattened, seldom exceeding the size of a dime or a quarter-dollar. They spread peripherally, inclining to dry and crust in the center. The course of both these lesions was rapid, disappearing in four or eight days, followed by crusting and pigmentation.

The general condition remained fair, there being no marked febrile disturbance, although the appetite was impaired, and the patient was weak, nervous, and much distressed in mind and body. With the cessation of new lesions the itching and burning declined, but did not leave entirely. The treatment consisted of a generous diet, with saline laxatives and small doses of arsenic and strychnia, together with anti-pruritic lotions of carbolic acid and tar. The man remained in the hospital several weeks longer, during which time he improved with remarkable rapidity. I can not, however, attribute the recovery altogether to the remedies used, knowing well as we do the singularly arbitrary course the disease usually pursues.

About three years afterward (December 20, 1882) I received a letter from Dr. Kollock (under whose care the patient had since been), stating that he had not seen the man for a year, but that, "according to last accounts, he had improved markedly in general health as well as locally under a tonic treatment. The eruption has appeared at longer intervals, and is confined to smaller areas. He seemed to derive great relief from the application of a lotion containing corrosive sublimate and alcohol." Since this date I have heard nothing.

The case represents more particularly the bullous variety of the disease, although its multiformity, as in almost all instances, was repeatedly shown. As I have so recently described this remarkable disease in a paper* read before the

* Abstracts may be found in the "N. Y. Med. Jour.," May 17, 1884, p. 562, and in the "Phila. Med. Times," May 17, 1884, p. 603.

American Medical Association, comment here is scarcely necessary. It may be stated, however, that the case illustrates the vesicular and bullous lesions as they usually occur in the course of the disease, the latter predominating. The resemblance to pemphigus is obvious, but I think it will be seen that the process is different, and that it can not be viewed as a variety of this disease.

A CASE OF GASTROSTOMY, WITH REMARKS ON THE AFTER-TREATMENT OF THE OPERATION.

By G. E. BUSHNELL, M. D.,
ASSISTANT SURGEON, UNITED STATES ARMY.

The patient, a man fifty-eight years of age, presented himself for treatment in December, 1881. Difficulty in deglutition had first been noticed the preceding August. The dysphagia had rapidly increased, and for two months he had been restricted to a diet of liquids. There was a history of syphilis. Upon exploration of the œsophagus, a stricture was encountered at a point about opposite the cricoid cartilage, which admitted with difficulty Otis's bulbous urethral sound No. 17. No tumor could be detected by palpation of the throat. The stricture, which was very firm and about half an inch in length, was gradually dilated by means of the bulbous urethral sounds until the tube of a stomach-pump passed it readily. Deglutition was so much improved by the dilatation as to negative the possibility of the existence of another more deeply situated stricture. After passing the stricture, the dilating instrument seemed to move freely in a cavity; yet, when pushed on, it met with resistance, and the patient complained of great pain and an intolerable tearing sensation. The stricture tending to contract rapidly, it was thought advisable to dilate it more widely than could be done by means of the tube of the stomach-pump. No suitable instruments being at hand, a very efficient dilator was improvised by the use of the transparent part of what is popularly known as "lemon candy," which was softened by heat and molded into the proper shape about the looped extremity of a stout iron wire. The "candy dilators" were well borne, and by their use the stricture was gradually dilated until its caliber exceeded an inch in diameter. No hemorrhage and but little pain ever resulted from the dilatation. Suddenly, without apparent cause, the patient began to expectorate great quantities of odorless pus; the act of swallowing excited such spasms of choking that food could no longer be given by the mouth, and there was complete intolerance of any instrument. The patient stated that he had had similar but less severe attacks, which lasted a week or longer. He was put to bed and fed *per rectum* with peptonized foods. The expectoration gradually diminished in amount, but became dark-colored and fetid. Swallowing continued to be impossible, and the attempt to pass a small tube through the stricture, for the injection of food, was unsuccessful. The patient, who was failing rapidly, now urged the performance of gastrostomy, which he had previously refused. The operation was performed by the writer on February 24, 1882 (the twenty-fourth day of exclusively rectal alimentation), with the assistance of Dr. J. C. McGuire, Acting Assistant Surgeon, U. S. Army, and Dr. G. W. Monroe, of Bozeman, M. T. The patient having been etherized, the usual incision was made parallel with the borders of the ribs of the left side, and all hemorrhage was carefully checked before dividing the transversalis fascia. The peritoneum, which was separated from the overlying tissues at least half an inch by atmospheric pressure, was slit up on a director and its edges grasped by forceps. The

abdominal walls, hitherto much sunken, having risen by virtue of their elasticity now that air was admitted into the peritoneal cavity, the latter became literally a "cavity," at the bottom of which the left lobe of the liver and the stomach were visible lying at the depth of more than an inch. Air passed in and out of the wound with an audible whizz at each respiration. The stomach was drawn up and found to be flaccid and voluminous, and its walls exceedingly thin. It was attached to the edges of the wound by sutures of silver wire, and a loop of silk was passed through the center of its exposed portion at the situation of the proposed opening. A small rod was inserted into the loop to aid the stitches temporarily in supporting the organ. Antiseptic precautions were strictly observed during the operation, and the carbolic spray was kept playing in the room, but not directly upon the wound. Temperature of patient at completion of operation, 4 p. m., 96.4° F.; pulse 96. At 7 p. m., temperature 97.5°; pulse 104. A few drachms of peptonized beef and milk were introduced into the stomach through a hypodermic needle, as suggested by Langenbuch. At 9.30 p. m., temperature normal, pulse 88. Four ounces of the same mixture were injected through the needle the next morning (February 25th), and this injection was supplemented by enemata of peptonized food and water during the day. The wound appeared healthy, and adhesions were forming rapidly. The general condition of the patient was not worse than before the operation. On February 26th an attempt to introduce the hypodermic needle produced a slight hemorrhage, apparently from the adhesions, and the procedure was abandoned. A small incision was made through the wall of the stomach and a new soft urethral catheter was inserted, tied in, and closed by a pinch-cock. Through this tube small quantities of peptonized food were frequently administered. The patient seemed to gain slightly in strength, but was tormented by a severe spasmodic cough, and complained of increased pain in the throat. On February 28th some of the stitches which had begun to cut out were removed. The stomach-tube, which at first fitted tightly, gradually became loose and permitted leakage of the contents of the stomach.

March 2d.—The patient not so comfortable. At the night-dressing, stomach seen to have settled down somewhat in the wound. The adhesions, however, were still firm. The stomach contents, of a dark-brown color and offensive odor, oozed freely from the opening. They were removed and the stomach washed out by means of a siphon.

March 3d.—Patient sinking rapidly. Temperature, which had varied but slightly from the normal since the operation, at 10 a. m. was 104.5°, pulse 156; 12.30 p. m., temperature 99.6°, pulse 130; 5 p. m., temperature 102.6°. Marked dyspnea developed about noon and continued until the patient's death at 6.15 p. m. An autopsy was made the next day in the presence of Dr. McGuire and Dr. Monroe. Body much emaciated. Left lung normal; right lung contained an old cavity in apex the size of a hickory-nut. Pleuritic adhesions at this point. Air-cells infiltrated with pus in numerous small and distinct areas throughout middle and inferior lobes ("Schluckpneumonie" from tracheal perforation?). Aortic valves calcified. A large, tough, yellow blood-clot extended through right auricle and ventricle and far into pulmonary artery. Deep lymphatic glands of thorax black and hard like lumps of coal. Liver and spleen normal. Capsule of right kidney adherent; otherwise kidneys apparently healthy. Local adhesive peritonitis about wound of operation uniting stomach to abdominal parietes. The remainder of the peritonæum perfectly healthy. Stomach, much dilated, contained several ounces of brownish fluid. Its walls very thin. Inflammatory thickening of the part comprised within the sutures. Larynx normal. In the œsophagus a stricture one third of an inch in diameter, commencing at a point

slightly below the level of the cricoid cartilage and extending downward half an inch. The tissues which formed the stricture of a bluish-gray color and very firm, almost cartilaginous in consistency. Below the stricture, for a distance of nearly four inches, the walls of the œsophagus, in their entire circumference, eaten away by deep, ragged ulcers, with gray floor dotted with granular bodies. Small perforation into trachea in the median line. Posteriorly the disease extended to and involved the vertebral periosteum. The œsophagus, trachea, and larynx have been presented to the Army Medical Museum. The specimen is No. 1,727 of the Medical Section.

An examination of the after-history of patients subjected to gastrostomy when much reduced by starvation often leaves the student in doubt whether any benefit has been derived from the introduction of food into the stomach after the operation. Those who escape the dangers of the operation soon die of exhaustion, for which the progress of the primary disease does not always furnish an adequate explanation. The progressive failure of the vital powers is largely to be ascribed to the difficulties which the enfeebled stomach encounters in resuming its functions. Peristalsis is interfered with by the stitches and the broad adhesions. Adhesions are a well-recognized cause of dilatation, and the starved stomachs of gastrostomized patients must be peculiarly unfitted to overcome such hindrances to their activity. The exposed portion of the organ becomes more or less inflamed from exposure to the atmosphere and the irritation of the wound discharges. Its circulation is impeded by the stitches which surround it. The circulation of the entire stomach becomes less active proportionately with the diminution of the muscular contractions. Statistics showing four deaths from gangrene of the stomach in one hundred and thirty-seven cases of gastrostomy (Professor S. W. Gross, "Medical News," December 1, 1883) prove that it may even be completely arrested. The innervation of the stomach is probably affected by the irritation of the stitches and the unwound exposure to the air. Amid such disturbance neither the secretion of gastric juice nor the absorption of peptones can be expected to take place normally. There is danger that food will gravitate into the splenic end of the organ and remain there to ferment.

That stagnation of the stomach contents does often occur has been shown in the history of many cases. To avoid this, and to assist the feeble digestive powers as much as possible, I would make the following suggestions, derived for the most part from the treatment of dilatation of the stomach: Let all food be thoroughly converted into peptones before administration. After forty-eight hours place the patient upon his right side after feeding, that the food may gravitate toward the pylorus.

As an experiment, it would be well to add hydrochloric acid to the food, if Leube's view is correct—that it is increase of acidity which enables the contents of the stomach to pass the pylorus. Wash out and empty the stomach frequently by means of a siphon. To spare the stomach, supply the water needed by means of enemata. It is, perhaps, worth noting that my patient, who received a quart of water daily *per rectum*, with bits of ice to suck *ad libitum*, never complained of the thirst which surgical writers speak of as adding so much to the sufferings of œsophageal stricture.

THE ARCHITECTURE OF THE SPINAL CORD, AND ITS RELATIONS TO MEDICINE.

By AMBROSE L. RANNEY, M. D.,
PROFESSOR OF APPLIED ANATOMY IN THE NEW YORK POST-GRADUATE
MEDICAL SCHOOL AND HOSPITAL.

(Concluded from page 37.)

It will be seen in this diagram that the motor tracts composing the column of Türcck and the crossed pyramidal tract of each lateral half of the cord (if traced upward in the diagram) become united in the medulla (one decussating and the other not) and then pass to the cerebrum. Each of these subdivisions of the motor tract gives off branches to the gray matter of each spinal segment. These branches unite with the motor cells of the anterior horn of the corresponding side through the net-work of Gerlach (Fig. 21). Subsequently these branches are continued from the bodies of the motor cells to the anterior root of the spinal nerve of the same side, as the "axis-cylinder process" of each cell. The motor tract derived from the cerebrum, therefore, is *constantly depleted*, in regard to the number of fibers of which it is composed, as it descends the cord. It finally terminates in the motor cells of the last spinal segment. By the interpolation of a motor cell for each fiber in the conducting path from the brain, every spinal segment is enabled to exert an *automatic action* upon the muscles supplied by its motor filaments; yet, at the same time, the brain can overpower this automatism when necessary, by means of its connection with the spinal cells, and exercise its control over the same muscles independently of the spinal segment. In some forms of disease, in which the controlling influence of the brain is impaired or destroyed, the spinal segments (left free to act without restraint) give rise to an exaggeration of the tendon-reflexes. This condition is of great clinical interest.

In disease of the spinal cord, all the muscles associated with the segments of the cord attacked are not equally paralyzed or atrophied in some cases, thus demonstrating that some are more easily disturbed by central influences than others. Allen has collected several reported cases of special interest in this connection: That reported by Charcot and Jeffroy of infantile paralysis, followed by death in the fortieth year, exhibited atrophy of both psoas muscles, the pectoralis major, deltoid, and triceps of the left side, and the deep flexors of the fingers of the right side. A case reported by Barth showed an atrophy of the supinator of the left forearm, and the quadratus femoris and gastrocnemius of both sides. Vulpius mentions a case in which all the muscles of the right leg, except the extensor communis digitorum, were fatty; in the thigh, the rectus femoris and the vastus internus were fatty, and the vastus externus was not.

Certain clinical facts can be adduced to support the view that the extensor nerves are associated with centers within the cord that become exhausted under depressing influences, as in the case of lead and diphtheritic poisoning, sooner than the centers governing the flexors. It is also well recognized that the flexor muscles are the chief agents in pro-

ducing various forms of post-paralytic contracture and deformity. When descending degeneration exists high up in the fibers of the crossed pyramidal columns, the arm gradu-

FIG. 21.—A DIAGRAM DESIGNED TO ILLUSTRATE THE CONNECTIONS OF THE MOTOR AND SENSORY CONDUCTING TRACTS WITH THE SPINAL NERVES. (Modified from Bramwell.) The lettering is the same as in Fig. 20. M, motor fibers of the anterior root of a spinal nerve; S, S', sensory fibers of the posterior root.

Note that the course of S and S' are not the same. Some sensory fibers pass through the posterior horn of the spinal gray matter, and others through Burdach's column. The direct cerebellar column is connected with Clarke's column of cells. The two pyramidal tracts are united with the motor cells of the anterior horns of the spinal gray matter.

ally becomes flexed upon the chest, the forearm becomes flexed upon the arm, and the hand flexed upon the forearm. Subsequently the lower limbs exhibit similar effects of muscular contracture, flexion again predominating over extension. The normal excess of power of the flexors over the extensors may partly explain the characteristic deformities that ensue when the fibers of the lateral columns are involved in degenerative processes, but we are forced to recognize also a peculiar susceptibility of the extensor nerves to impairment of their function from causes that do not affect the flexor nerves to the same degree, if at all.

The diagrams represent the *sensory nerve-fibers* as undergoing a total decussation and passing upward to the brain in the column of Goll of the opposite half of the spinal segment. It shows that the sensory nerve-fibers pass first from the posterior root to the column of Burdach; and, after traversing its substance, a decussation by means of the gray commissure of the cord takes place. Now, this arrangement probably admits of some modification. It is by no means proved, as yet, that all of the sensory fibers of the cord decussate. Again, it is still a matter of uncertainty where the main sensory tracts can be definitely placed, and whether more than one may not exist. Finally, some clinical facts as well as those lately obtained by experimentation favor the view that the sensations of pain, touch, and temperature do not follow the same paths of conduction in the spinal cord. It is highly probable that all the sensory nerves eventually decussate, but it is believed by many physiologists of the present day that some of the sensory

FIG. 22.—A DIAGRAM DESIGNED BY THE AUTHOR TO REPRESENT THE VARIOUS PATHS OF SENSORY CONDUCTION IN THE CORD.

A, direct cerebellar column, receiving fibers from Clarke's column (E) of the same side; B, Goll's column, receiving fibers from the opposite nerve-root by means of the posterior gray commissure; C, ganglion-cell of anterior horn joining with its sensory fibers; D, sensory tract of Wroeschloff, Gowers, and Ott, in the lateral column of the cord.

fibers ascend for a greater or less distance within the substance of the corresponding lateral half of the cord before they cross to the side opposite to that upon which they entered it. Some authorities also believe that the sensory nerves connected with the tendons, muscles, and fasciæ pass through Burdach's column of the same side, while those connected with the skin traverse the gray matter of the posterior horn. They thus endeavor to explain the abolition of the deep or tendon reflexes in locomotor ataxia, because that condition is characterized by a change in the columns of Burdach that would tend to impair the conduction of any filaments passing through its substance.

We may, therefore, draw the following deductions:

1. The fibers of the nerve-roots eventually pass to and enter the gray substance of the cord, but not by the same channels in all cases. In the case of the posterior roots, some fibers probably form an exception to this rule.
2. The fibers of the anterior roots become joined to the processes of the nerve-cells of the gray matter. This state-

ment can not be made with the same degree of positiveness in respect to the fibers of the posterior root.

3. From the ganglion-cells of the gray matter the fibers of the anterior roots pass to the brain through the white matter by one of three channels: 1. By entering the lateral columns of the same side (the so-called crossed pyramidal column). 2. By entering the anterior column of the same side (the column of Türck). 3. By passing to the opposite anterior and lateral columns through the white commissure of the cord (decussation within the cord). Fig. 21 shows the first two, and Fig. 17 the third, in a diagrammatic way.

4. The processes of the ganglion-cells of the cord take every variety of direction. Some anastomose with other cell-processes of the same side; some join with those of the opposite half of the cord, by means of the gray commissure; some join directly with the fibers of the nerve-roots; some join with the fibers of the main conducting tracts that are connected with the brain; while a few pass into the white columns of the cord and then appear to ascend within them.

5. Individual fibers of the anterior and posterior nerve-roots probably meet each other indirectly by means of the processes of the nerve-cells.

6. A few fibers of the anterior roots appear to traverse the gray substance and then to pass into the anterior part of the lateral column. Their function is not known.

7. The fibers of the posterior roots probably reach the cells of the posterior horn by means of a net-work of fibers.

8. Fibers pass from Clarke's column to the direct cerebellar column of the same side.

9. Some medullated fibers appear to arise directly from Gerlach's network of fine fibers, rather than from a ganglion-cell directly.

Brown-Séquard was led to believe, before sensory nerves to muscular tissue were demonstrated, that the paths of the so-called "muscular sense" entered at the anterior nerve-roots and passed up in the anterior columns of the gray substance of the cord. As this is not now believed to be true, it is not to be classed as an exception to all other paths of sensory conduction. It is probable that the fibers concerned in the sensation of touch and those of muscular sense do not decussate within the cord (Schiff and Brown-Séquard).

Clinical Reports.

NINETY-NINTH STREET RECEPTION HOSPITAL.

Rattlesnake Bite.

(From Notes kindly furnished by Dr. A. M. SPALDING, House Surgeon.)

J. R., a powerful man, forty-seven years old, of Irish birth, a professed "snake-charmer," was bitten by a rattlesnake at about 4.30 P. M., on Sunday, July 13, 1884. The reptile was of the variety known as the Mexican "diamond snake" (*Crotalus adamanteus*), said to be nearly ten feet long and as big round as the arm of a well-developed man. The patient was accustomed to handling the snake in question. Having relinquished his hold of the snake's neck, in order to demonstrate to the bystanders

that the fangs had not been interfered with, he attempted to regain his hold by sliding his hand along the reptile's back, when the latter turned upon him and inflicted a wound upon his right hand, on the dorsal aspect, between the first and second metacarpal bones. The man at once drank a pint of whisky, and a physician made three incisions, laying the wound open. In the course of half an hour after the bite was inflicted the man fainted and was carried to a police-station. There he vomited the whisky, and at once drank a quart more. Two hours after the injury the ambulance was sent for.

The ambulance surgeon, on his arrival at the station-house, found the man covered with a cold, clammy perspiration, his aspect being that of great anxiety and despair. His mind was clear; his pulse was rapid, feeble, and almost imperceptible; his respirations were hurried and labored. His restlessness was extreme, and he was unable to remain in one position more than a minute at a time. He complained of a feeling of great constriction across the chest, and of terrible pain near the umbilicus. The hand was swollen, of a purplish color, had a peculiar odor, and was bleeding freely from the incisions. The swelling extended only to the wrist. The hand felt cold to the touch. The patient complained of agonizing pain extending up the arm.

On his admission to the hospital, a half-hour later, his condition was about the same. He was put to bed, and began at once to have involuntary evacuations of the bowels—at first solid, then solid and liquid feces, and finally pure blood of an arterial color. This purging continued, at intervals of a few minutes, for two hours; then the movements gradually became less frequent. With the purging there was constant vomiting—first of the contents of the stomach, and then of blood, also of a bright color. By this time the swelling had extended up the arm to the elbow, and on the palmar surface the tint had gradually changed from a marble hue to a darker color; the color of the hand was also becoming darker. The glands in the axilla were swollen and very painful; the man's voice was husky and weak; his tongue was dark-red and dry; his pupils were dilated, and did not respond readily to light. The depression of all the vital forces was more marked; the radial pulse could hardly be felt; the restlessness and all the symptoms before specified had also increased; there was constant thirst, with agonizing pain in the arm, extending up over the chest and stomach, as well as over the back in the region of the kidneys.

A hypodermic injection of liquor ammoniac—ten minims—was given immediately on his admission, and seemed to strengthen the pulse a little. Besides this, frequent subcutaneous injections of whisky were given—thirty minims in each—until about two fluidounces had been given in all. At this time it was impracticable to administer anything by the mouth or by the rectum, on account of the vomiting and purging. There was little change in his condition through the night, but toward morning he appeared to be weaker. The respirations were still rapid, but not quite so labored.

About noon on Monday, the day after his admission, the pulse could be felt only as a little fluttering; weakness was more marked; the patient spoke with difficulty, and gave up all hope of recovery. The swelling of the arm had increased, and now extended to the trunk, the color being dark-bluish, due to effusion of blood. This discoloration also extended over the right side of the chest. There was no delirium, and the mind remained clear to the last. He gradually grew weaker, all the symptoms continuing, until he died, about 8 o'clock in the evening, of exhaustion and heart-failure, the heart ceasing to beat several seconds before the respiration stopped. During the day, the vomiting and purging having subsided, he drank about a pint

of milk, and throughout the day he quenched his thirst with frequent draughts of hot tea.

Post-mortem Examination, forty hours after death, by Dr. MICHAEL J. R. MESSEMER.—There was great extravasation of blood into the tissues of the arm, extending about the shoulder, and over the right side of the body, down to the groin in front, as if from severe bruises. Both lungs were congested and oedematous, the congestion being most marked in the upper lobe. The heart was pale and flabby, but contained neither ante-mortem nor post-mortem clots. About a fluidounce of blood was found in each of the pleural cavities, and half an ounce of serum in the pericardium. The stomach was highly congested and partly filled with blood. The right kidney was of one third the normal size, the left kidney being considerably larger than normal. The spleen was normal; the liver congested, but otherwise normal. The brain was heavy and healthy, with slight congestion and extravasation, and gave evidence of an old pachymeningitis. Death seems to have been due to syncope, from septicæmic gases entering the right auricle by way of the vena cava.

[By the courtesy of Dr. Messemer, to whom we are indebted for the notes of the post-mortem examination, we hope to be able to give the results of the examination of the blood in a future issue.]

Book Notices.

The Hip and its Diseases. By V. P. GIBNEY, M.D., Professor of Orthopaedic Surgery in the New York Polyclinic, etc. New York: Bermingham & Co., 1884. Pp. 412.

For the general practitioner, the term hip-joint disease includes almost every affection of the articulation, and he can find but comparatively little on the subject in works on general surgery. There is to many something mysterious about diseases of the hip, and, although their knowledge of affections of the other joints may be clear and correct, so soon as a case of lameness from trouble with the hip joint comes under their observation they are apt to be driven in despair to an instrument-maker's catalogue for aid. Up to the present time, we do not know of a single volume that treats of diseases of the hip—and they are many—in a thorough manner. Most of those that have appeared from time to time are far from satisfactory, many of them, indeed, seeming to have been written chiefly to advertise some new splint. The book now under consideration, therefore, written by one who has had a vast amount of clinical experience in the subject, calls for something more than a brief notice.

The author tells us in the preface that the hospital with which he is connected "is known as one of extreme conservatism," and that the plan of treatment followed out corresponds with a strict definition of the term expectant.

The book is divided into eighteen chapters, and is embellished (?) with sixty-four woodcuts. The first, or introductory chapter, is devoted to a general outline of the work, and contains an excellent schedule for reporting cases. Chapter II takes up the anatomy of the hip joint, and is compiled from the works of Gray, Quain, and Morris. In Chapter III sprains and contusions of the hip are considered, and then diagnosis and treatment. Chapter IV deals with those obscure affections, the neuroses of the hip. In the diagnosis of these troubles the author lays great stress on the importance of spinal tenderness and a neurotic family history. Chapter V is devoted to rheumatism of the hip and to chronic rheumatic arthritis. Under

the first of these two heads the author includes myalgia, which we think somewhat confusing. The term he employs should be restricted to articular troubles. He objects to the word myalgia, but uses none other in its place. Chapter VI is entitled "Coxo-femoral Periarthritis." In Chapter VII bursitis is treated of—a subject of great interest, and one to which sufficient attention has not been paid. Chapter VIII deals with acute primary synovitis. In Chapter IX the author treats of acute primary epiphyseitis, meaning "an acute primal lesion at the diaphyseo-epiphyseal junction," the osteitis extending quickly and destructively from this point to the epiphysis, so that necrotic diastasis soon follows, and the force of the lesion is practically spent upon this portion of the femur, shortening being an early symptom. Traumatic diastasis of the head of the femur, a very rare occurrence, is also considered. Periostitis and malignant disease of the hip are considered in Chapter X. In the author's experience, the former has been due to traumatism.

Chapter XI is devoted to the pathology of chronic articular osteitis, commonly known as hip-joint disease, coxalgia, tubercular disease, etc. The author employs the term first mentioned because it best represents the pathology and conveys a distinct meaning. The lesion is a chronic inflammation of the bones entering into the formation of the hip joint, the vast majority of the cases occurring in childhood. The author thinks that the initial lesion is an osteitis interna; that the head and neck of the femur are more often involved than the acetabulum; that it is rare for a single center of ossification to be involved; that the osteitis is a rarefying osteitis, and may terminate in caries atonica or caries sicca, the former being the more frequent; and that the synovitis is secondary, being simple if developed by contiguity, and purulent if due to perforation. The ætiology of the disease is considered in Chapter XII. The author is satisfied that in all cases there is a predisposing cause, the tubercular or strumous diathesis; that these chronic joint diseases can not occur in a non-strumous child; that the diathesis may be hereditary or acquired; that falls and other injuries are not a cause of the disease, except in the subjects of the diathesis; and that in many cases there is absolutely no exciting cause.

Chapter XIII takes up the clinical history and the complications of chronic articular osteitis. Dr. Gibney adopts the common division of the disease into three stages. The symptoms of the first stage are lameness, slight deformity, reflex phenomena, atrophy of the limb, and pain. There may be slight lameness, occasional pain, a trifling amount of deformity, and resistance to passive motion beyond a certain point; or there may be scarcely a symptom present except the limp. On the other hand, the suffering may be severe, and acute symptoms may be developed suddenly on trivial provocation, with extreme lameness and signs of distension of the synovial sac. This state of things may pass off in the course of a few days, under the influence of rest, and the parts may almost resume their normal condition. The evolution of the disease may be, and often is, slow, the first stage extending over a long period before the second one is ushered in. Pathologically, the first stage corresponds with the disease of the bone, the joint itself not being involved. The second stage corresponds pathologically with perforation, either into the capsular ligament or into the circumarticular tissues, and is marked by increasing deformity. Gradually or rapidly it passes into the third stage, and then there is real shortening, the deformity is mainly due to changes in the shape of the bones, abscesses may form, and dislocation may occur. Chapter XIV deals with the diagnosis of hip disease, and great stress is laid on the desirability of an early diagnosis and of greater precision in methods of examination. This is one of the best chapters in the book.

Chapters XV, XVI, and XVII are devoted to the treatment of the disease. From the peculiarity of the author's experience, as explained in our quotation from the preface, he is personally most conversant with the expectant treatment—this, therefore, is the most unsatisfactory portion of the book. He advises non-interference with abscesses; they may open of themselves and burrow where they will. In regard to operative measures, the author seems to advocate excision in extreme cases. For the deformity, after a cure, Volkmann's cuneiform osteotomy between the trochanters is advised.

We have devoted considerable space to an enumeration of the general contents of the book in order to give some idea of its scope. An immense amount of labor has been expended in its production, and, as regards pathology and clinical history, it is certainly the best work on the subject we have ever seen. Indeed, it is extremely valuable. The chapters on chronic articular osteitis are particularly worthy of praise, being quite up to the teachings of practical surgeons of the present day. In regard to some points exception will no doubt be taken; for instance, as to the management of abscesses, which in this locality should be treated as they would be if situated in connection with any other articulation. Although their course is very little under control, we can limit their extension and counteract the tendency to burrowing by opening them, and that is no small gain. The let-alone treatment seems to us to be a development of conservatism that is not to be recommended. In regard to osteotomy for the correction of deformities left by the disease, we think that a division of the femur below the trochanter minor is a better operation than Volkmann's, because it frees the psoas and iliacus, and thus allows of the limb being placed in a better position.

Dr. Gibney is to be congratulated on the very satisfactory manner in which he has accomplished his task. We wish that we could say as much for the publishers, but we are forced to declare that we have seldom met with such cheap-looking and unsatisfactory illustrations in a medical book as are to be found in this volume. We are sorry that so good a treatise appears in so shabby a garb.

The Evolution of Morbid Germs: a Contribution to Transcendental Pathology. By KENNETH W. MILLICAN, B. A. Cantab., M. R. C. S., Fellow of the Medical Society of London. London: H. K. Lewis, 1883. Pp. 107.

If the value of a book is to be measured by its size, Dr. Millican's little brochure will appear insignificant enough; but, if we judge it by the suggestiveness of its matter and the importance of the new lines of thought which it opens up, our estimate of its worth will doubtless be considerably enhanced. If we add that the author's treatment of the matter and methods of reasoning are cautious and judicial rather than partisan in their tone, we shall have said enough to recommend the work to the notice of all who are interested in its subject.

The contents of the book may be summarized in two propositions: first, that by a process of development, induced mainly by alterations in conditions of environment, a germ, which usually produces by its activity the symptoms of one specific disease, may be so altered as to produce those of another distinct disease; in other words, that the bacterium of scarlet fever may be converted in a different disease into the bacterium of scarlet fever. The second proposition is that, by a similar process of development, an entirely innocent organism may be converted into one of specifically noxious properties—i. e., that a scarlet-fever bacterium may be generated from a simple microscopic germ, which ordinarily is devoid of pathological significance. The evidence for these propositions is

partly *a priori*, partly the result of clinical experience, and, in presenting it, the author adduces a number of curious instances pointing to the heterogeneity and absence of specific character in the so-called essential diseases. Of course, it is the amassing of evidence of this sort that the theories here advanced are to be ultimately tested; and it is greatly to be wished that extended investigation could be carried on in this field of such fruitful promise. In the mean time, it must be confessed that our knowledge of what may be called the natural history of epidemic and contagious diseases is sadly defective and in need of revision.

One argument stated by Dr. Millican is particularly suggestive. It is addressed to those who deny that the Darwinian theory of gradual development can be applicable to such rapid changes in the life history of the bacteria as are necessitated by his hypothesis. To this he answers that these evolutionary processes do not so much require causes working over long periods of time as causes working upon many successive generations; and, inasmuch as a thousand generations of bacteria may rise and fall in the course of a few days, slight changes of environment affecting every one of these generations successively are competent to cause great changes at the end of say a week's time.

Another pregnant result embraced in the author's hypothesis is that it does away with what he not inaptly calls the bugbear of the germ theory—the question of *de novo* origin. The latter, viewed in the light of his propositions, is only “evolution of function.”

Of course, when all is said, the hypothesis, so fascinating in its completeness and so satisfactory in the readiness with which it solves knotty points formerly insoluble, is an hypothesis still, and needs the corroboration of carefully ascertained facts. The book is useful, at all events, if only in pointing out the way which we must follow, if these facts are to be compiled.

BOOKS AND PAMPHLETS RECEIVED.

Syphilis and Pseudo-syphilis. By Alfred Cooper, F. R. C. S. Eng., Vice-President of the Medical Society of London, etc. London: J. & A. Churchill, 1884. Pp. xvi-339. [From P. Blakiston, Son & Co., Philadelphia. [Price, \$3.50.]

On Visceral Neuroses; being the Gulstonian Lectures on Neuralgia of the Stomach and Allied Disorders. Delivered at the Royal College of Physicians, in March, 1884, by T. Clifford Allbutt, M. A., M. D. Cantab., F. R. S., etc. Philadelphia: P. Blakiston, Son & Co., 1884. Pp. viii-103. [Price, \$1.50.]

Notes on the Opium Habit. By Asa P. Meylert, M. D., Member of the Medical Society of the County of New York, etc. Second Edition. New York: G. P. Putnam's Sons, 1884. Pp. 37. [Price, 40 cents.]

Cauterets, ses eaux minérales et leurs effets curatifs. Par le Dr. Duhoureau, pharmacien de première classe, etc. Paris: Ve. A. Delahaye & Lecrosnier, 1882. Pp. 109.

Quarterly Report of Medical Officers, United States Army, with their Stations and Duties, as reported to the Surgeon-General July 1, 1884, or at date of last report received at this office.

Fermentation in the Human Mouth; its Relation to Caries of the Teeth. The Influence of Antiseptics, Filling Materials, etc., upon the Fungi of Dental Caries. The Fungi of Dental Caries; their Pure Cultivation and Effect upon Lower Animals. By Dr. W. D. Miller, Berlin, Germany. [Reprint from the “Independent Practitioner.”] [Price, 50 cents.]

NEW YORK, SATURDAY, JULY 19, 1884.

PREPARATIONS FOR THE CHOLERA.

IN view of the probability of a visitation of cholera, the State Board of Health of New York has issued a special circular in which, while it takes the very sensible ground that quarantine measures should not alone be depended upon, it does not, on the other hand, sneer at them and vilify them, as has come to be too much the habit with sanitary boards in this country. Indeed, the circular distinctly alludes to the fact that, although the disease was brought to the New York quarantine station in the autumn of 1865, it was not until the following spring that it gained a foothold in the city. The whole tone of the circular is in keeping with the view that quarantine is one of our defenses against cholera, but that it is only an outpost, so to speak, and that the inner lines, where the hand-to-hand conflict is to be waged, are in every way to be strengthened by cleanliness, especially in the matter of drinking-water.

The circular points out that the European sources of cholera are now at least equal to what they were in 1865, and that the means by which the disease is likely to be conveyed across the Atlantic are decidedly greater than they were then. One need not be an alarmist to recognize the truth and the bearing of these statements, however at variance they may be with the jaunty suggestions of certain officials of the steamship lines to the effect that the "cholera scare exists only in the newspapers." It is true that the cholera may not reach the American coast this summer, and that, if it does, it may be stopped at the quarantine stations; but the probability seems to be that neither of these possibilities will intervene to shield us from an outbreak of the disease. The board, therefore, wisely calls upon every city, town, and village to make preparations to resist and limit the spread of any outbreak: to make careful sanitary inspections; to drain all stagnant pools and low grounds near dwellings; to clean all sewers and house-drains; to cleanse and disinfect cellars, privies, and all filthy places; and to examine and protect the purity of drinking-water.

This advice, of course, is such as the careful and the intelligent will at once admit to be wise, and will proceed to follow to the extent of their ability; but the question at once arises as to what can be done to compel some heed being paid to it by those who are not disposed to do so voluntarily, but upon whose course not only their own safety but that of their fellow-citizens largely depends. To show how far it is empowered to control local sanitary bodies, the board has obtained an opinion from the Attorney-General, and has issued it in the form of a supplementary circular. The gist of the opinion is that the State Board of Health is supreme over local boards, and that, in case the latter prove inactive in suppressing nuisances dangerous

to the public health, in the opinion of the State board, it may compel them to take measures for their suppression, employing mandamus proceedings, if necessary, as prescribed in section 2,067 of the Code of Civil Procedure. It seems, however, that, before such proceedings are resorted to, it will be necessary for the State Board of Health to notify the town board, through the Supervisor, that, in the judgment of the State board, the nuisance exists in the town, and that the town board is required to take proceedings for its removal or abatement. Some months ago the State board found itself in a position where it thought it could do no more than "request" a powerful railway corporation to provide means of draining a stagnant pool caused by the obstruction due to one of its viaducts. It is to be hoped that the board will now feel its hands so strengthened that it may deal summarily with offenders.

CHOLERA AND QUARANTINE.

THE national limitation of diverse views as to the advisability of attempting to stay the march of cholera by quarantine is somewhat puzzling. When we consider that the English, almost without exception, whether sanitarians, Government officials, or others, look upon the plan of fighting cholera by means of quarantine restrictions as absurd, if not cruel, while, on the other hand, with equal unanimity the same classes in every other country of Europe not only regard the English opinion as untenable, but in many instances go so far as to countenance measures on the part of their respective governments calculated by their severity to make up for the English laxity—when we consider these facts, the obvious inference is that the English, alone of all civilized nations, either have hit upon a truth which others must have been blind indeed not to see, or, however involuntarily and insensibly, have subordinated their reasoning powers to their commercial pride. It is not unlikely that the course of the disease in Europe this summer may demonstrate which of the two suggestions is correct, and it will be fortunate for us if experience gained in America does not contribute to the solution of the question.

That a quarantine against cholera is apt not to be so effective as is desired, and perhaps not so efficient as against some other pestilential diseases, may be admitted without our conceding the soundness of the English position. A measure may be relatively very inefficient, and yet contribute somewhat to the desired result. On that principle, we must deprecate the disposition manifested in some quarters to discredit quarantine in advance by the cry that it never yet stopped cholera. Cholera is a disease that pre-eminently follows the course of commerce, and, if any given outbreak is to end otherwise than by the natural dissipation of its forces, it seems reasonable to suppose that it must be checked by some device which limits the part played by commerce in its transportation. But, however we may look at the main question, there can be no doubt that the English doctrine has this one good effect, that it tends to bring the importance of civic sanitation prominently forward in the public mind.

But it is not at all certain that our English friends are so

confirmed in their distrust of quarantine measures as to omit their enforcement altogether. We learn from an editorial article in a recent issue of the "Medical Times and Gazette" that, under the revised cholera regulations, an officer of the customs may detain any vessel on its arrival in English waters if he has reason to suspect that it is infected with cholera; and, having done this, he must give notice of the detention of the vessel to the sanitary authorities, who must cause their Medical Officer of Health, or some other medical man, to visit and examine the vessel. Or a Medical Officer of Health may visit and examine any vessel that he may suspect of being infected with cholera, or of having come from some infected port. When a medical officer has certified that a ship is infected, no one can leave it without the medical officer's permit; and, should any person be found to have cholera, he must be sent into hospital. In doubtful cases, the patients may be detained on board the ship or in hospital until the nature of their illness has been clearly made out; and provision is made for the disinfection of the vessel and of all infected clothing, bedding, etc. Sanitary authorities have been appointed at the English ports, and it is stated to be the duty of their sanitary officers to deal, in accordance with the prescribed regulations, with all infected ships and all cases of infectious disease coming into port. "These regulations," the "Times and Gazette" adds, "which are the outcome of our present knowledge and experience of the modes by which the spread of cholera can most certainly be prevented, are now in force, and will remain in force not for any definite period only, but until they are repealed."

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 15, 1884:

DISEASES.	Week ending July 8.		Week ending July 15.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	1	0	3	0
Typhoid Fever.....	9	3	7	3
Scarlet Fever.....	42	13	45	7
Cerebro-spinal meningitis....	4	4	2	1
Measles.....	171	32	181	26
Diphtheria.....	34	18	29	13

The Cholera in Europe.—During the week the outbreak in France had shown no abatement, but rather an increase, especially in Marseilles, where it has produced the utmost consternation, more than fifty thousand of the inhabitants being estimated to have fled. As we go to press, it is reported that a few cases have occurred in Paris, but there is as yet no authentic news of anything like an epidemic prevalence in that city. The rumored appearance of the disease at Lyons is denied. On the 14th it was reported that two cases had occurred in the Russian town of Poltava. Dr. Koch is said to have expressed the opinion that the cholera was introduced into France by some English vessel which failed to report cases that it had on board. Still more stringent measures of protection are being undertaken by the various European governments, and the people of Great Britain seem to be losing their sense of security.

In our own country also commendable activity is being dis-

played. Our consuls at London, Liverpool, Marseilles, Havre, Bordeaux, Bremen, and Hamburg have been instructed by the State Department to appoint competent medical officers at once to inspect all vessels and passengers leaving those ports for this country; they are instructed to refuse clean bills of health in all cases in which the medical officer recommends that course; and notice has been given by our consul at London that vessels without a clean bill of health can not be admitted into American ports. The Surgeon-General of the Marine-Hospital Service states also that customs officers along the coast have been instructed not to admit passengers' baggage unless it can be shown that it did not leave any of the infected ports after June 20th. Provision is being made, too, for the disinfection of suspicious cargoes of rags, and for the prevention of the entrance of vessels laden with cargoes of that sort, as well as of the indirect importation of infected rags through Canada and other foreign countries. The quarantine officers in Louisiana have been ordered by the State Board of Health to detain all vessels arriving from any ports where cholera exists. On Tuesday a steamship reached Sandy Hook, having left Marseilles on the 28th of June. She was detained, very properly, although she had left Marseilles before there had been any cholera there. The President of the National Plumbers' Association has addressed a communication to the members of the association, suggesting that they should act as an auxiliary sanitary corps, under the direction of local boards of health.

The Transmission of Cholera by Railway Travel.—The Lyons *Société nationale de médecine*, as we learn from the "Gazette hebdomadaire de médecine et de chirurgie," has recommended the enforcement of the following rules for preventing the transmission of cholera by railway travel in France: 1. The Mediterranean system shall at once be divided into two sections: that of the contaminated districts, and that of the non-contaminated districts. The point of division between them shall be that express station which, being situated in the non-infected district, is nearest the boundary. 2. Each of these systems shall have special cars, which shall not pass the point of division under any circumstances. The point of division shall be the place of transfer of all passengers leaving or entering the infected zone. 3. Passengers coming from the infected district shall be conveyed in cars reserved exclusively for them. These cars shall be placed at the rear of the train. The cars at the head of the train shall be reserved exclusively for way-passengers. Passengers of the two classes shall be strictly prevented from entering the cars which are not intended for them. 4. When the terminus is reached, the cars that have transported passengers from the infected district shall immediately be disinfected. 5. Baggage from the infected district shall be disinfected *en route* by fumigation with sulphur burned in stationary pans in the baggage-cars. 6. Baggage-cars which are not transferred shall, in addition to the continuous sulphur fumigation on the way, be disinfected outside, at the point of division, with a solution of sublimed chloride of zinc or some other powerful disinfectant. 7. Hand baggage shall likewise be disinfected, at the point of division, by exposure to the fumes of sulphur for at least twenty minutes. 8. The baggage of a passenger attacked with cholera, or who has died of the disease *in transitu*, shall, on the arrival of the train, be subjected to a special and more thorough disinfection.

A Concealed Case of Small-pox was the subject of search on the part of the medical officers of the Board of Health on Tuesday and Wednesday. The patient had escaped from Greenpoint, and been taken across the East River in a coach, but he could not be found in the house at which the driver of the coach stated that he had left him. It is suspected that the

man's relatives are secreting him, and, if this should turn out to be the case, the board will prosecute the offenders under the Penal Code.

Yellow Fever in Mexico.—Advices from the City of Mexico, by way of Galveston, state that on the 15th inst. the fever was raging at Guaymas, and that there had been several cases at Mazatlan. It was added that as yet the disease had not appeared on the Gulf Coast this year.

"Rough on Rats" has caused the death of another person, this time by suicide, the victim being a German shoemaker living in Newark, N. J.

A Nuisance Abated.—The State Board of Health is to be congratulated on having succeeded in causing the abatement of at least one nuisance, in the shape of a cream of tartar factory at Stapleton, Staten Island.

Alleged Ill-Treatment in a Lunatic Asylum.—A story is told by a citizen of Syracuse, lately discharged from the State Lunatic Asylum at Utica, of brutalities practiced upon himself and other inmates of the institution of so revolting a character that we prefer to believe them in great measure founded only in his imagination. The story is said to be generally credited in Syracuse, however, and the moral of the occurrence seems to be that the administration of our asylums should be so manifestly above reproach as to make the popular belief in such tales impossible.

The Niagara University.—The "Buffalo Medical and Surgical Journal" learns that a very advantageous piece of property has been acquired for a new building for the medical department, near the Grosvenor Library.

The Honorary Degree of LL. D., we are informed, was conferred on Dr. N. C. Husted, of this city, by Syracuse University at its recent annual commencement.

The Medical Society of the County of Richmond.—At the annual meeting, held July 2d, the following-named gentlemen were elected officers for the ensuing year: Dr. R. Henry Golder, president; Dr. T. J. Thompson, vice-president; Dr. E. D. Connelley, secretary and treasurer; Dr. Ambrose, Dr. Beyer, and Dr. Wood, censors; and Dr. F. E. Martindale, delegate to the State society.

Recent Paris Thesis.—The "Progrès médical" gives the following dates and titles of recent *thèses de Paris*: May 21st: A Contribution to the Study of the Nervous Phenomena of Typhoid Fever, by M. Riberolles; On Lymphangitis in Diseases of the Skin, by M. Pavrel. May 23d: Puerperal Eclampsia, by M. Chambert; The Bichloride and the Biniodide of Mercury in Obstetrics, by M. Bastaki. May 24th: Corrosive Sublimate in Obstetrics, by M. Beuve; Remissions in Locomotor Ataxia, by M. Bordéremy; A Study of Four Cases of Fatty Hypertrophic Cirrhosis, by M. Rosenblith; A Contribution to the Study of the Treatment of Tinea Tonsurans, by M. Thomas; Hæmatoma of the External Auditory Meatus, by M. Tétard; Alcoholism and Cirrhosis, by M. Jaladon. May 29th: A Contribution to the Study of a Rare Complication of Hydatids of the Liver, by M. Faillé; The Treatment of Nephritis with Digitalis, by M. Jaulin; A Contribution to the Study of Intestinal Obstruction without Mechanical Obstacle, by M. Thibierge; On Blennorrhœa treated with the Sulphurous Waters of Bagnères-de-Luchon, by M. Doit; A Contribution to the History of Malingering in the Military Service, by M. Gentilhomme. May 30th: The Study of Ophthalmoscopy in Meningitis, by M. Bouchut; The Connection between Vaccinia and certain Diseases of the Skin, and their Reciprocal Influence, by M. Moulinet; On Prolonged Applications of Antiseptic Spray in the Treatment of certain

Surgical Affections, by M. Charles; A Contribution to the Study of Gummy Periostitis of the Scapula, by M. Folliot. May 31st: The Typhus or Plague of Athens, by M. Lallot; A Study of the Clinical Forms of Renal Cancer, by M. Patino Luna. June 5th: A Contribution to the Study of Persistent Asthma, by M. Sagrandi; Hydrorrhœa, and its Import as a Symptom of Cancer of the Uterus, by Mlle. Coutzaride. June 6th: A Contribution to the Study of Hepatic Syphilis, by M. Bourred; On Epithelioma of the Floor of the Mouth, by M. Faure. June 12th: A Study of Fatty Cirrhosis, by M. Bellangé; Hæmatoma of the External Auditory Meatus, by M. Tétard; The Ætiology of Scurvy in Prisons, by M. Mercier. June 13th: On the Form of the Pelvic Excavation considered from an Obstetrical Point of View, by M. Boissard. June 13th: A Study of some Cases of Uterine Malformation, with special reference to Pregnancy and Labor, by M. Humbert; A New Method of Chloroformization by Means of Titrated Solutions, by M. Lambert; Artificial Alimentation, by M. Houel; A Study of Pulmonary Congestion as a Complication of Injuries of the Brain, by M. Sourice. June 17th: Artificial Alimentation, by M. Humbert; Pulmonary Congestion Complicating Cerebral Injuries, by M. Houel; A Study of a Case of Sudden Death by Pulmonary Embolism, by M. Motel. June 18th: The Channels of Access of Tuberculosis, by M. Verchère; Hæmophilia, by M. Hernandez; Corrosive Sublimate in Obstetrics, and especially in Fœtal Putrefaction, by M. Bonnet. June 19th: The Results of the Application of Rousset's Law to the Calvados, by M. Vallette; The Œdèmes of the Arthritic Diathesis, by M. Testelin. June 20th: The Clinical Forms of Intermittent Fever in Children, by M. Benoit; Blennorrhagic Follicular Inflammation in Women and its Treatment, by M. Bouchet; The Conditions of Surgical Interference in External Localized Tuberculosis, by M. Condray; The Solution of Stone in the Bladder, by M. Portafax. June 26th: On Ulceration of Arteries due to Contact with Pus, by M. Flous; Experimental Researches on the Discovery of Tuberculosis in Bones, by M. Castrosoffi. June 27th: On Muscular Shocks, by M. Colaneri; Osteo-periostitis following Typhoid Fever, by M. Turgis; Syphilis and Prostitutes, particularly with regard to the Pigmentary Syphilide, by M. Maireau; Affections of the Buccal Mucous Membrane in their relations with the State of the Teeth, by M. Trichet. June 30th: Lacerations of the Cervix Uteri, by M. Jaquetot; The Therapeutical, Chemical, and Physiological Properties of the *Hamamelis virginica*, by M. Guy. July 2d: The Best Mode of Treating Purulent Pleurisy, by M. Guinard; The Local Treatment of Psoriasis with Chrysophanic Acid, by M. Dérobert. July 3d: Ptosis, and particularly its Treatment by the Method of Supplementing the Levator Muscle of the Upper Lid by the Frontal, by M. Beauvois; The Treatment of Goitre with Iodoform, by M. Thiroux. July 4th: Carcinoma of the Peritoneum, by M. Mongrid; Congenital Serous Cysts of the Neck, by M. Bacna. July 5th: Ocular Rheumatism and some of its Manifestations not usually known, by M. Barneua; The Relations of Peritonitis to Atrophic, Hypertrophic, and Fatty Cirrhosis, by M. Husson.

The Late M. Dumas.—We learn from the "Progrès médical" that a public subscription has been started in France for the purpose of erecting a monument to the memory of M. Dumas, and that the Paris Faculty of Medicine will take part in the movement.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 6, 1884, to July 12, 1884:*

Promotions to date from July 2, 1884.

PERIN, GLOVER, to be Assistant Surgeon-General, with rank of Colonel.

SMITH, ANDREW K., to be Surgeon, with rank of Lieutenant-Colonel.

MIDDLETON, PASSMORE, to be Surgeon, with rank of Major.

CLEMENTS, B. A., Major and Surgeon. Also directed to relieve Surgeon J. P. Wright of his duties as Acting Medical Director Department of the Missouri. Par. 1, S. O. 188, Headquarters Department of the Missouri, July 8, 1884.

Promotions.

To be Assistant Surgeons with the rank of Captain, after five years' service, in accordance with the act of Congress of June 28, 1874:

KANE, JOHN J., Assistant Surgeon, June 3, 1884.

BANISTER, JOHN M., Assistant Surgeon, June 3, 1884.

APPEL, AARON H., Assistant Surgeon, June 3, 1884.

RICHARD, CHARLES, Assistant Surgeon, June 3, 1884.

CARTER, W. FITZHUGH, Assistant Surgeon, June 3, 1884.

BIRMINGHAM, H. P., First Lieutenant and Assistant Surgeon. From Fort Bayard, N. M., to Fort Bliss, Texas. Par. 3, S. O. 187, Headquarters Department of the Missouri, July 3, 1884.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the Navy during the week ending July 12, 1884:*

LUMSDEN, G. P., Passed Assistant Surgeon. Ordered to U. S. S. Wyandotte.

PERBONS, R. C., Passed Assistant Surgeon. Detached from U. S. S. Wyandotte, and placed on waiting orders.

Marine-Hospital Service.—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service—April 1, 1884, to June 30, 1884:*

BAILHAQUE, P. H., Surgeon. Detailed as chairman of board to examine candidate for appointment into the Revenue Marine Service, May 17, 1884.

VANSANT, JOHN, Surgeon. To proceed to Empire City, Oregon, as inspector, April 2, 1884.

HUTTON, W. H. H., Surgeon. Granted leave of absence for twenty-five days, May 14 and June 9, 1884.

MILLER, T. W., Surgeon. Granted leave of absence to attend the meeting of the American Medical Association, May 1, 1884. To proceed to Pittsburgh, Pa., Ashtabula, Ohio, Buffalo, N. Y., and Detroit, Mich., as inspector, May 10, 1884.

WYMAN, WALTER, Surgeon. To proceed to Crisfield, Md., as inspector, April 11, 1884. Detailed to represent the Marine-Hospital Service as delegate to the American Medical Association, April 17, 1884. Detailed as president of board for physical examination of candidates for appointment as cadets in the Revenue Marine Service, May 20, 1884. To examine cadet-graduates Revenue Marine Service as to physical qualifications, May 31, 1884. Detailed as member of commission to inspect United States buildings at quarantine station on the Delaware River, June 16, 1884.

AUSTIN, H. W., Surgeon. Granted leave of absence to attend the meeting of the American Medical Association, May 2, 1884.

GASSAWAY, J. M., Surgeon. When relieved by Passed Assistant Surgeon Mead, to proceed to Portland, Me., and assume charge of the Service, April 16, 1884. Granted leave of absence for thirty days, May 28, 1884.

STONER, G. W., Passed Assistant Surgeon. When relieved by Surgeon Gassaway, to proceed to Cairo, Ill., and assume charge of the Service, April 16, 1884. When relieved by Surgeon Gassaway, to report in person to the Surgeon-General, June 20, 1884.

IRWIN, FAIRFAX, Passed Assistant Surgeon. Granted leave of absence for twenty-one days, June 19, 1884.

MEAD, F. W., Passed Assistant Surgeon. When relieved by Assistant Surgeon Devan, to proceed to Philadelphia, Pa., and assume charge of the Service, April 16, 1884. Detailed as recorder of board for physical examination of candidates for appointment as cadets in the Revenue Marine Service, May 20, 1884.

CARTER, H. R., Passed Assistant Surgeon. To inspect unseviceable property at the San Francisco Hospital, May 24, 1884.

WHEELER, W. A., Passed Assistant Surgeon. To inspect unseviceable property at the Chicago Hospital, May 24, 1884.

BENSON, J. A., Passed Assistant Surgeon. Granted leave of absence for thirty days, April 14, 1884. When relieved by Passed Assistant Surgeon Stoner to report to him for temporary duty, May 19, 1884.

BANKS, C. E., Passed Assistant Surgeon. Detailed as member of board to examine physically candidate for appointment into the Revenue Marine Service, May 17, 1884. To inspect unseviceable property at Baltimore, Md., New York, N. Y., and Boston, Mass., May 26 and June 2, 1884.

BENNETT, P. H., Assistant Surgeon. Granted leave of absence for twenty days, June 28, 1884.

DEVAN, S. C., Assistant Surgeon. To proceed to Port Townsend, W. T., relieve Passed Assistant Surgeon Mead, and assume charge of the Service, April 14, 1884.

URQUHART, F. M., Assistant Surgeon. Granted leave of absence for thirty days, May 22, 1884.

YEMANS, H. W., Assistant Surgeon. To report to Captain M. A. Healey for duty as medical officer during cruise of Revenue Cutter Corwin, April 16, 1884.

GLENNAN, A. H., Assistant Surgeon. To proceed to Mobile, Ala., for temporary duty during sickness of Passed Assistant Surgeon Goldsborough, June 17, 1884.

Appointment.

BROOKS, STEPHEN D., M. D., of Massachusetts, having passed the examination required by the regulations, was appointed an Assistant Surgeon by the Secretary of the Treasury, May 15, 1884. (Dr. Brooks had previously served as an Acting Assistant Surgeon from March, 1883, to May, 1884.)

Society Meetings for the Coming Week:

TUESDAY, July 22d: Medical Society of the County of Putnam, N. Y. (annual).

Proceedings of Societies.

NEW YORK CLINICAL SOCIETY.

Meeting of March 28, 1884.

Dr. J. WILLISTON WRIGHT, Chairman for the evening.

Diffuse Suppuration of the Pelvis and Thigh.—Dr. L. BOLTON BANGS remarked, concerning the case that he had reported at the last meeting [see p. 26], that the improvement had been only temporary, that there was now hectic fever again, and that the patient was losing ground. The speaker's term of service at the hospital had expired, and consequently the patient was not now under his observation.

Chronic Abscess of the Neck connected with the Tonsil.

—Dr. ROBERT ABBE mentioned the case of a man who had been sent to him to be operated on for a tumor of the neck of three

years' standing. Apparently he had a glandular tumor, but, on closer examination, it was found to consist of a tense sac, and some very thick pus was withdrawn from it by means of an exploring-needle. An incision was made, and the sac was evacuated. It was then found that a sinus extended upward behind the jaw, into which a probe could be passed for several inches, without touching any dead bone. The sinus did not heal, and after a time a small calcareous mass, about as large as a pea, was discharged. Further probing showed that the sinus led up to the outer side of the tonsil, where the probe could be felt just beneath the mucous membrane. Subsequently five or six more of these small calcareous masses were discharged, and the sinus had now healed. The case seemed to be one of old inflammation of the tonsil with calcareous degeneration; the opening on the mucous surface having closed, burrowing of pus to the side, of the neck had followed.

The CHAIRMAN reported a case almost precisely the same which had come under his observation about ten years before. The patient was an elderly lady, and the swelling was supposed to be glandular. Incision and scraping were not followed by a cure, and there was a sinus that took precisely the same course as in Dr. Abbe's case. Calcareous masses were discharged, and the tract healed in about a year.

Dr. WALTER MENDELSON asked if any chemical examination had been made of the calculi, with a view of determining whether they were of gouty origin or not.

Dr. ABBE said they had not yet been examined.

Dr. E. G. JANEWAY remarked that these concretions usually consisted of carbonate and phosphate of lime, like those in the lungs, unless the patient was gouty.

Fracture of the Patella.—Dr. J. H. EMERSON related a case of fracture of the patella which he had treated the preceding summer, using adhesive straps and plaster of Paris. At the end of four months the treatment was discontinued, there being then no appreciable separation of the fragments. Four months afterward he was called to see the lady again, as she had met with a fracture of the other patella, and he then found the fragments of the bone first fractured separated two inches, but bound together by a strong ligament.

Dr. ABBE thought that such stretching of the ligamentous band happened not uncommonly, even in so short a time. It did not seem advisable, however, to keep the limb quiet for a longer time. The length of the ligament was not a criterion of the utility of the limb. He remembered a patient once shown by Dr. Frank Hamilton, in whom there was a separation of fully four inches when the knee was bent; yet the functions of the limb were perfect, so far as could be seen. The patient could walk up and down stairs with the greatest facility.

The CHAIRMAN remarked that, when one patella was broken, the other one was apt to be broken also sooner or later. In any misstep the patient always threw a great strain upon the sound limb, being so accustomed to favor the other one.

Retention of a Laminaria Tent in the Uterus.—Dr. EMERSON related the case of a young married woman who had come to his clinic complaining of repeated uterine hemorrhages. A history of pregnancy and of early abortion was elicited, and it was determined to dilate the cervix and explore the uterine cavity. The cervix was firm, and the uterus was slightly ante-flexed. Some difficulty was met with in passing the uterine sound. A laminaria tent two inches and a half long was introduced. On attempting to remove this, twenty-four hours later, the silk thread was pulled off, but the tent did not come away. Various attempts at dilatation and removal with forceps, etc., were unsuccessful. The cervix was then slit up half an inch on each side, but without success. A tampon was applied, and a dose of ergot was given. On the following day

the patient was anesthetized, and attempts were again made to extract the tent with forceps of a number of kinds, but to no purpose. The cervix was then divided freely, through the os internum, and just at that time the patient vomited, with the result of starting the tent, so that it was easily removed with a tenaculum. The retention of the tent had been due to the ante-flexion, which it had partially corrected. The patient was now doing well, and had had no bad symptom. The incised cervix had not yet been brought together.

Low Temperature in Pneumonia.—Dr. JANEWAY called attention to the significance of low temperatures in pneumonia. He had recently seen three cases, two of which proved fatal, and the third, which was still under observation, would probably result in the same way. The first case was that of a woman, fifty-five years of age, whom he had seen on the sixth day of the disease, hæmoptysis having given rise to the suspicion of phthisis. He found well-marked consolidation at the base of one lung, and some signs on the other side. The rectal temperature was only 100° F. The patient died on the ninth day. In the second case he saw the patient on the fourth day, and there had been no marked elevation of temperature. Here, also, the physical signs were plain. In the third case the highest temperature noted thus far had been 102°. Such cases used to be called asthenic pneumonia. For several days before taking to bed, the patients were often sick without any marked rational symptoms, or the symptoms might be misleading, like the hæmoptysis in one of the cases he had referred to; and yet they might die a day or two later. He thought this low temperature a bad symptom, although he had seen it followed by recovery. In the cases referred to, the pulse had been rapid—in the first one, from 150 to 160; in the second, from 120 to 130. He also called attention to the fact that apex pneumonias were often overlooked because the physician examined only in front, and the signs were not usually to be found there, but high in the axilla and behind. The percussion-note in front was often vesiculo-tympanic from imprisoned air. Many such cases were diagnosed as remittent fever.

Dr. J. E. WINTERS had seen acute pneumonia, complicated with pericarditis, in an old lady whose temperature did not go above 98.5° and much of the time remained at 97.5°. The patient recovered. Recovery took place in another case also, that of a lady of seventy, whose highest temperature was 99.75°. The pneumonia was at the apex. In a third case, in a patient of sixty-eight, the whole right lung was involved, there was delirium for ten days, but the highest temperature reached was 101.5°. In that case also recovery took place. From this experience, he was not inclined to look upon low temperature as so unfavorable a symptom as Dr. Janeway had indicated, but he agreed with him as to the obscurity often attending apex pneumonias. He had seen a child who had had three convulsions within an hour, and yet the temperature was not high, and the pneumonia was not extensive.

The CHAIRMAN had seen a child one afternoon which had been taken with convulsions in the morning. The temperature was 104°. Pneumonia was suspected, but no physical signs were found. The convulsions were repeated the following day, and in a few days the physical signs proved the correctness of the suspicion.

Dr. G. A. SPALDING mentioned the case of a baby six months old, with pneumonia, in which the temperature dropped within six or eight hours from 104° to 95° in the rectum the extremities becoming cold, as well as the nose and the ears. It was twenty-four hours before the temperature reached 97°. The case ended in recovery.

Dr. JANEWAY thought this was most probably a case of collapse from heart-failure.

Slowness of the Pulse in Acute Diseases.—Dr. GASPAR GRISWOLD mentioned two cases in which a very slow pulse had been noted, and asked the opinion of those present as to its significance. The first case was one of typhoid fever. The temperature ranged from 105° to 105.5° , but the pulse never rose above 100. For several days before death it was only 80. In the second case, one of intestinal obstruction, the pulse was only 54 for the greater part of the time, and several times dropped nearly to 40.

Dr. JANEWAY also had observed this state of the pulse in typhoid fever, and mentioned the case of a girl with this disease, complicated with myocarditis, in which the pulse ranged from 40 to 60. The patient ultimately recovered. He thought the slowness of the pulse was to be explained by degenerative changes in the substance of the heart, as in cases of fatty heart.

Constipation and Melancholia.—Dr. BANGS related the case of a gentleman, seventy-four years of age, who, while riding, was suddenly seized with a desire to evacuate his bowels. When he reached home he was unable to pass anything, and from that time for a year he suffered with the most obstinate constipation. Examination revealed a large mass, which nearly filled the rectum, situated about three inches from the anus. It was hard and firm and not sensitive on pressure, and there was no sign of ulceration. There was found to be a small opening through it, which was dilated so as to admit a No. 9 Wales's rectal bougie, and there was now no difficulty about the evacuations, but within the last few weeks the patient had lapsed into a state of great mental depression, had lost flesh rapidly, and was now truly melancholic. Although cancer might be suspected from the family history, no evidence of such a growth could be found on careful examination.

Dr. WINTERS mentioned a case of obstinate constipation with melancholia in a young man of nineteen, in whose case no other cause for the symptoms could be found than the gastro-intestinal disorder. He was treated for many months without any change, but finally the stomach and intestines returned to their normal condition, and with that the melancholia disappeared.

Dr. JANEWAY remarked that patients with melancholia were almost always constipated, and that it was hard to say in such cases which was the cause and which was the effect. In such patients all the functions were performed sluggishly.

Dr. MENDELSON mentioned a case that he had seen in the New York Hospital, in which delusions and obstinate constipation were associated, and in which the patient ultimately became really insane.

An Obscure Case of Dropsy was related by Dr. L. Emmett Holt: A lady, thirty years old, had been under observation for several months, suffering with chronic pelvic cellulitis and peritonitis. She gave a history of having had acute peritonitis several years before. During the interval she had suffered almost continuously with diarrhoea, which had been relieved only temporarily by treatment, but had had no dropsy. One morning she awoke and found her face greatly swollen, and in the course of the day the lower limbs became very oedematous, even above the knees. She could not wear her shoes, and only with the greatest difficulty a pair of loose slippers. The flow of urine was very free. There was a little nausea, with slight headache, but no vomiting. She was conscious of not feeling quite so well as she had felt for a few days before, but of nothing more. The bowels at this time were under control by astringents. She was seen after the dropsy had existed for two days. It was then beginning to subside, and there was none in the face, but it was still very marked in the legs and ankles. That was the first day that she had been able to button her shoes. She was not anæmic, but had a good color in her cheeks. No organic disease of the heart could be found, and she had never had

rheumatism. She was not hysterical, nor even what would be called nervous. At this time she was passing pale and limpid urine, of a specific gravity of 1.004, in which the heat-and-nitric-acid test revealed no albumin, and in which there was no deposit, nor any abnormal constituent to be found on microscopical examination. Two days afterward, another specimen showed a specific gravity of 1.022; it was of an amber color, and acid reaction, but contained no albumin and showed nothing abnormal under the microscope. This was a morning specimen. The dropsy had by this time quite disappeared. Several specimens of the urine were subsequently examined, but the specific gravity was never less than 1.020, and nothing was found in them by chemical or microscopical examination. There had been no return of the dropsy, and it was now two weeks since its first appearance. The case was presented for a diagnosis.

Dr. MENDELSON suggested some vaso-motor disturbance.

The Significance of Glycosuria in Connection with Disease of the Brain and Cervical Cord, and with Dementia Paralytica.—Dr. ALLAN McLANE HAMILTON's paper with this title, read in abstract at the preceding meeting [see page 1], was now brought up for discussion.

Dr. JANEWAY thought the aphasia of nephritis was the result rather of the arterial changes in the brain than of the changes in the kidney. Albuminuria and coma might just as well be owing to cerebral hemorrhage as to uræmia, as he had often had opportunities of demonstrating. Vaso-motor disturbances were very common in cases of Bright's disease, and often of a temporary character. Regarding the presence of sugar in the urine in epileptic coma, or in asphyxia of any kind, he had carefully tested for it in thirty cases. Although it was occasionally seen, it was always in very small quantity, and might be disregarded as a diagnostic sign. He would call attention to persistent occipital headache as an early sign of Bright's disease, and one which should always excite suspicion and lead to an examination of the urine. These patients were often treated for congestion of the brain.

Dr. BANGS asked whether the gynecologists would regard delay of the menses until the twenty-second year as a reason for suspecting kidney disease. He had recently seen such a case, and, in trying to find out some cause, discovered oedema of the right foot. The urine showed granular and hyaline casts. A history of scarlet fever eight years before, followed by dropsy, was obtained. Under the use of iron and the bichloride of mercury, the patient improved rapidly, and at the end of a year the menses appeared.

Dr. JANEWAY related a case which had come under observation on account of persistent headache following an attack of cerebro-spinal meningitis. The patient stated that, since the meningitis, but several years ago, another physician had found sugar in his urine. The sugar had afterward disappeared. A day specimen of the urine revealed a large amount of albumin, but no casts. Night and morning specimens were afterward examined, without even a trace of albumin being found. The urine passed during the day always contained it in large amount. The patient was taught to make the tests for albumin, and kept up a series of observations for a long time. He found that the albumin was always absent from the urine passed immediately on rising. If he took a sponge bath, or even read the paper for an hour, the urine passed afterward always contained albumin in considerable quantities. Any mental or physical effort was enough to make it appear. Casts were never found, and the quantity and specific gravity remained normal. His headaches were much improved by the use of ergot. The appearance of sugar, and subsequently of albumin, under the peculiar circumstances stated, he thought was in consequence of the old menin-

gitis. Dr. Janeway had seen another case in which the quantity and the specific gravity of the urine were normal, and there was no albumin, but after any severe exertion hyaline casts were present in quite large numbers, and sometimes granular casts. The heart was normal. The patient had no other symptoms of renal disease.

Dr. BANGS mentioned the case of a man who was much of the time in a varnish factory. His urine at these times was always albuminous and had the odor of violets. He was under observation for several years, and never had any albumin unless he had been exposed to the turpentine.

L. EMMETT HOLT, M. D., *Secretary*.

NEW YORK OBSTETRICAL SOCIETY.

(Meeting of February 19, 1884, concluded from page 51.)

Rupture of the Uterus; Laparotomy.—Dr. E. L. PARTRIDGE related a case of rupture of the gravid uterus—less on account of any unusual features which it presented than because of the rarity of the accident. The patient was a poor woman, under the care of a midwife who seemed to be an intelligent and honest person. She stated that the patient had been in labor since four o'clock in the morning, and that she had been with her since five o'clock. She had made examinations from time to time, and had distinctly felt the head presenting. The cervix was dilated to perhaps two inches and a half. The patient, while standing, not having had any specially severe labors, suddenly exclaimed that something had given way, and immediately lay down upon the bed. The midwife again made an examination, and could not feel the head, as she had previously. She sent for Dr. W. E. Forest, but, he being out, she sent for another doctor, who remained by the patient two hours without appreciating the condition. This was about 11 A. M. Dr. Forest then came and found rupture of the uterus, and sent for Dr. Partridge, who arrived perhaps an hour later. The pulse was about 120, not excitable, but fairly strong. There had been comparatively little external hemorrhage, but more than one would expect in ordinary labor. Palpation showed that the uterus was pretty well contracted and situated toward the patient's left side. The fetus was evidently on the right side. An extremity could be distinguished through the abdominal wall, and the finger was passed upward through the cervix, through a rent in the uterus, toward the right side of the abdomen, where a foot could be distinguished, the head being in close proximity, but on a higher level. It seemed, therefore, that the head had been presenting, and that when the rupture occurred the head pressed through the rent and left the feet presenting. It was decided to open the abdomen and remove the child, although some of the physicians present favored extraction through the vagina. The operation was performed at 4 P. M. by Dr. Forest. The incision in the abdominal walls extended from the umbilicus down to the symphysis. The bladder was found spread out like an apron, and, when lifted, extended up nearly as high as the navel. A small amount of urine had been withdrawn with the catheter just before the operation. The peritonæum presented an appearance as if there were gangrenous intestine beneath, but, after a moment, the cause of this appearance was recognized to be liquid blood, situated beneath that membrane. The peritonæum was opened, and most of the free blood in its cavity escaped before the child was removed. The child was easily extracted. The placenta was entirely within the abdominal cavity. The child was large, and, of course, was dead. The uterus was well contracted. The rent began on the left side, near the cervix, and extended to the median line, thence upward to within a third of the dis-

tance to the fundus anteriorly. The child lay on the right side. The peritonæum was stripped up from the edge of the rent in the uterus, so that it could be lifted from the wound to the distance of an inch in one place. The peritonæum had yielded in front of the head before it became lacerated, and then laceration took place not exactly in a line with the rent in the uterus. The rent in the uterus was closed with silk, five or six stitches being employed. The abdomen was very readily cleansed of the small amount of blood which was present. No liquor amnii was present. The abdominal wound was then closed. The pulse was now 115, whereas it had been 120. It seemed, therefore, that the immediate result of removal of the child from the abdominal cavity was an improvement in the condition of the pulse. Dr. Partridge did not see the patient after this time, but he was told that she lived for four days, and then died of peritonitis. It was recognized when the abdomen was opened that it would have been utterly impossible to extract the child through the vagina, and Dr. Partridge thought it might be said in a general way that, when rupture of the uterus had existed for some time, one could be pretty sure that the uterus would be found so contracted that the child could not be drawn through the rent. Any way, it would be a question, if the child had escaped completely into the abdominal cavity, whether, under any circumstances, it would be proper to seize it and draw it through the uterine rent, for the procedure would certainly result in making the rent considerably larger. For that reason, then, if for no other, he thought it would be unadvisable to withdraw the child through the vagina. The pelvis was normal in development; the patient had borne children before. There was no apparent reason for the rupture. The uterine tissue seemed to be quite firm, and the stitches held perfectly well. There was no oozing from the uterine wound after it was closed. No autopsy was made.

Dr. Lusk inquired if Dr. Partridge thought there would have been any advantage in removing the entire uterus.

Dr. PARTRIDGE said he had often thought of the propriety of such a procedure, on general principles, but the question had not been raised in this case.

Dr. Lusk said that, inasmuch as the laceration was principally in the lower segment of the uterus, the organ never contracted down upon it well, and he had often wondered if it would not be a safer procedure to take out the entire uterus. In the two cases which he had witnessed, the patients at first were in excellent condition for operation. The uterus was not removed, however, and they finally died after an operation similar to the one which Dr. Partridge had performed.

Dr. WARD thought Dr. Partridge voiced the sentiment of the profession of to-day when he said it was unwise to attempt to extract the child through the vagina, especially after the occurrence of such a rupture as he had described. He believed that, in the majority of cases which had been reported, the child had escaped almost entirely through the rent, and under such circumstances he thought laparotomy was the only proper resource, and the suggestion made by Dr. Lusk, with reference to removal of the uterus, was one which deserved serious consideration. He should certainly act upon that suggestion should he again be called to see such a case as he witnessed with Dr. Partridge some years ago, in which the uterine walls were so thin and friable that it was with great difficulty that the sutures could be made to hold.

Dr. W. R. GILLETTE thought the question raised by Dr. Lusk was one which might be discussed theoretically all night, and we should know as little at the end of that time as now regarding its possible practical value. It seemed to him, however, an unnecessary risk to submit the patient to, without promising corresponding advantages. It was just as possible to thoroughly

cleanse the abdominal cavity and the uterine cavity after sewing up the ruptured uterus as after laparotomy for any other purpose, and it seemed to him that removal of the uterus under such circumstances would simply add other dangers to those which already existed.

Dr. Lusk referred to the danger of gaping of the uterine wound, and added that the longer the stitched surface was, the greater this danger would be.

The PRESIDENT said that so few cases had been reported giving the results of suture in Cæsarean section that we could hardly base conclusions upon them. In the case reported by Dr. Garrigues, however, complete union had taken place, as shown by the autopsy a short time after the operation.

Dr. GILLETTE said that several years ago he was requested, by an old and quite well-known practitioner, to take charge of a woman in labor, in a rear tenement-house. The doctor had been in charge all night, and was desirous of relinquishing the case, saying that he was about to leave town and could not continue with it. Dr. Gillette consented to take the case, but insisted upon the doctor's remaining to examine the patient with him and give him the benefit of his knowledge of what had occurred through the night. While this preliminary conversation was going on, Dr. Gillette remarked that there were no ejaculations indicating pain upon the part of the patient. His suspicions and fears were considerably aroused, and were not allayed when, upon stepping into the lying-in chamber, he saw the patient looking like wax, with a pinched, worn, anxious expression, very feeble, and quite content from the fact that the pains had suddenly and entirely ceased some two hours previous.

Upon making an examination, he found evidences from palpation of a ruptured uterus, with the escape of the fetus into the abdominal cavity. The ordinary vaginal digital examination revealed no presenting part, but, upon introducing the hand, the worst fears were realized, and the case was thoroughly diagnosed as a typical one of rupture of the parturient uterus. It was, as memory told him, almost similar to the case related by Dr. Partridge. In those days little was known or thought of laparotomy, and Dr. Gillette proceeded at once to seize the foot of the child and deliver by version and extraction. It was accomplished easily. The placenta was removed by easy extraction. To shorten the story, the patient recovered without an alarming symptom, notwithstanding every disadvantage of squalor, filth, and inattention in the way of nursing was present. The case was not related for the purpose of advocating the method of treatment pursued in preference to laparotomy and the more modern and antiseptic surgical methods of treating such cases. On the contrary, Dr. Gillette thought the latter procedure was the proper one in the light of the advanced state of obstetrical practice of the present day. Indeed, it would seem almost impossible, with our present views, for a woman to recover under the conditions which must have existed in the case related. There was no doubt of the complete rupture of the uterus, as the hand was passed completely into the abdominal cavity; and how recovery could take place with the abdominal cavity full of blood, amniotic fluid, vernix caseosa, and what not, was one of those mysteries which must for ever confront the theories of antiseptics and drainage.

Dr. Lusk said that cases of rupture of the uterus had been reported in which the peritonæum was simply lifted up, but left intact.

Dr. GILLETTE supposed the peritonæum must have been ruptured in his case; at any rate, the child had escaped entirely out of the uterine cavity.

Dr. H. T. HANKS had once been called to a case of rupture of the uterus, under the care of a midwife, and on his arrival had found the patient in a collapsed condition. He was sur-

prised at the ease with which he could pass the hand through the uterine rent, seize the feet, and extract the child through the vagina. He remembered a case in the practice of Dr. Barton, of Orange, Mass., in which the child had also entirely escaped into the abdominal cavity with the exception of the feet. In this case also the doctor was able to pass the hand through the rent and extract the child. That patient recovered. Dr. Hanks thought that, where the rent was sufficiently extensive and the uterus had not so contracted but that the hand could be passed through the rent, extraction through the vagina should be preferred to laparotomy.

Dr. PARTRIDGE said, further, with regard to removal of the uterus, that he did not know that there would be any special disadvantage in doing it, and in this case it was feasible, but, on the other hand, he could not say that the procedure would offer any special advantages unless the condition were such as in the case referred to by Dr. Ward, in which the uterine tissue was so degenerated and softened that sutures would not hold; or in case the uterine rent was so lacerated and irregular that perfect coaptation could not be obtained, and it might be expected that subsequent leaking would occur through it into the peritoneal cavity; or in cases of pelvic deformity in which subsequent pregnancy would be undesirable. Women who had sustained rupture of the uterus had lived to bear children.

The point which Dr. Lusk wished to make was that, if it was dangerous to sew up the wound in Cæsarean section, because there would be a tendency afterward to sloughing and gaping of the wound, allowing of the escape of the uterine contents into the peritoneal cavity, these dangers would be even still greater in a case of rupture of the uterus; and the question was, whether it would not be better to remove the entire organ, especially as the patient was usually in good condition for an operation.

The PRESIDENT inferred from the discussion which had taken place that it was the voice of the society that, if the uterine rent were in a position to give favorable results from suture, the proper procedure would be to sew it up; but that, if the rent were in such a location, and the uterus in such a condition, as not to favor union, then probably removal of the uterus would be the better method to adopt. Each case, therefore, would have to be treated on its individual merits.

HENRY J. GARRIGUES, M. D.,

B. F. DAWSON, M. D.,

FRANK P. FOSTER, M. D., *ex officio*,

Committee on Publication.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Meeting of June 17, 1884.

The President, Dr. JOHN A. McCORKLE, in the chair.

Ephemeral High Temperatures in Young Children.—Dr. HENRY N. READ read a paper with this title. [See page 57.]

Dr. SAMUEL F. ARMOR remarked that the paper and cases reported brought out distinctly a clinical fact of great practical interest, namely, that high temperature in children was not nearly so significant of serious disease as in adults. A child, as we had seen, might frequently have a rapid rise of temperature, even to 105° F. or more, and as rapid a subsidence without reference to remedies. It was evident, therefore, that age had something to do with this rapid though not dangerous evolution of animal heat. And just here an interesting, although at present a somewhat speculative, question arose as to the genesis of fever. In the investigation of the question of animal heat we at once confronted one of the most singular and, to his mind, most mysterious facts in the universe, and that was the con-

stancy of temperature in health, even to the fraction of a degree, under most varying circumstances. Whether we ate much or little, took exercise or remained at rest, lived in a tropical climate or at the poles, on the mountain-top or in the valley, the result was the same—the temperature was 99°. It followed that there must be some inhibitory, regulating power in the body which preserved this normal standard of warmth. When physiology settled this question we should know more about the genesis of fever. What was it that disturbed this inhibiting, regulating power? He would not pretend to enter this field of speculative inquiry. Two main theories had been presented: The one was that it originated in living tissues—that it was an expression of the molecular activity of various forms of protoplasm—i. e., that it essentially consisted in “increased tissue metamorphosis.” The other was that it originated in disorder of the nerve-centers—that certain portions of the nerve-centers acted as reflex, inhibitory “heat-centers”—that these centers acted as the governor of the steam-engine acted. Some recent contributions to the nervous origin of fever had been made to the Smithsonian Institution by Professor Wood, of Philadelphia, and at the late Medical Congress in London. Dr. Armor said he was proud of the distinguished compliments paid by that learned body to our distinguished countryman for the work he had done in that direction. Dr. Wood had reached the conclusion, by a series of carefully conducted experiments, that the *pons* was the regulating, inhibitory thermic center, and that the increased tissue metamorphosis was a secondary fact. And still the question was open as to whether the rise of temperature was due to increased heat production, or to a retention of heat. The fever, as had been well stated in the paper, simply reduced itself to a question of the difference of the heat-producing and the heat-evolving powers of the body. Therapeutically, we tried to make these two forces compensatory to each other. Now, what was the effect produced by the various causes of fever on the “heat-center” of the nervous system? Was it over-tension in the nerve-centers, or the reverse? What was the disturbed interaction between the nervous system and the blood and tissues in the febrile process? When we were able to settle this question definitively, we should know more about the genesis of fever. It had been suggested theoretically, and certainly with great plausibility, that when, from disease or injury of the “heat-centers,” their power of maintaining tension was abolished, the affinities of the blood and tissues had unrestricted play. Hence the super-oxidation, the increased tissue change, and the pyrexia.

We might not know why in early and infantile life this disturbance of equilibrium more readily took place than in adult life. And yet we knew the fact that the brain and nerve-centers were peculiarly impressionable in early life; hence easily disturbed, giving rise to ephemeral forms of fever, convulsions, etc. We found also that elevation of temperature was much more easily subdued in infantile than in adult life, and by simpler means. He heartily agreed with the author of the paper in condemning the constant resort to large doses of quinine, aconite, digitalis, veratrum, etc., in the treatment of these ephemeral high temperatures. First try the simpler remedies. Without reference to unsettled theoretical questions, we could often make the heat-evolving compensatory to the heat-producing powers by the judicious use of baths. Quite recently he had seen persistent convulsions in a child with a temperature of 105° rapidly relieved by the simple application of an ice-pack to the head and the nape of the neck. The temperature came down rapidly, with a prompt subsidence of the convulsions. While he was in Edinburgh, some years since, Dr. Keith, the eminent ovariotomist, had called his attention to the fact that, by cold local packs to the base of the brain and to the neck, he could generally re-

duce the temperature about 2°—all, perhaps, that he required after surgical operations.

In this connection Dr. Armor spoke of the use of the cold bath in summer complaints of children. With a hot, dry skin and a temperature of, say, 105°, it had been his invariable practice for years to resort to the cold bath. Theoretical objections might be urged against it. But certainly no febrifuge was so effective. The temperature usually came down rapidly under the use of the bath, with an amelioration of the abdominal symptoms. Injections of cold water were also attended with benefit. Dr. Armor, in conclusion, repeated the remark that these simpler means of controlling fever, especially with children, were often more effective, and certainly less dangerous, than the mere potential drugs so often administered.

Dr. JEROME WALKER spoke of his use of the cold bath in the high temperatures of children. He liked it much as a general febrifuge. His experience had been pretty large in the treatment of diseases of children in the Sea-side Resort. He spoke also of the use of oily inunctions for the same purpose. He had known the temperature to be reduced 3° by that means alone.

Dr. ARMOR had also been accustomed to reducing temperature by means of inunctions. With children, especially in some forms of eruptive fevers attended by high fever, it often proved a soothing and valuable febrifuge. But he rarely found it reduce the temperature more than 1.5° or 2°. If the temperature was very high and the skin dry, he preferred the cold bath.

Indigestion and Intestinal Catarrh in Infants.—Dr. E. H. BARTLEY read a paper with this title. [See page 58.]

Dr. WALKER said that, having agreed to say something at this meeting, and having had no time in which to write an article, he had looked over Dr. Bartley's paper, and, while there were many good things in it, especially the remarks about the antiseptic treatment of diarrhoea, he was almost bewildered by the multitude of suggestions. The fact was, there was so much diversity of opinion among practitioners in regard to the causation and treatment, that it was high time that a systematic study of the diarrhoea of children should be made by a well-appointed committee, which would take the time necessary for a thorough investigation. One had only to glance at the various text-books to see a variety of views and diverse methods of treatment. He was reminded of two investigations, and diverse reports on the same, made in England several years ago, of an endemic of cholera infantum by equally good committees. A few years ago he had had occasion to examine the death certificates at the office of the Board of Health, and had been surprised at the variety of causes of death assigned in connection with diarrhoeal diseases—gastro-enteritis, catarrh of the bowels, diarrhoea from dentition, cholera infantum, summer diarrhoea, summer complaint, gastritis, enteritis, vomiting and diarrhoea, etc.

Every year at the Sea-side Home filled-out blanks were received from physicians giving the cause of sickness, for example, as cholera infantum, when the closest inquiry failed to show that there had been any vomiting, or that the diarrhoea had been watery—the cholera of infancy. The looseness with which terms were used, as shown by these blanks, was astonishing.

In regard to the classification of diarrhoea, a simple and quite accurate method seemed to him to be: 1. Simple or irritative diarrhoea, due to undigested food or other irritant. 2. Inflammatory diarrhoea. 3. What might be called nervous diarrhoea, due to weakened nerve-force and loss of muscular tone. All forms of diarrhoea were influenced by excessive heat and by changes in temperature, but it was not necessary that there should be decided changes in temperature to produce diarrhoea; “devitalized air” in dwellings, as Dr. Richardson, of London, called it, was sufficient.

In speaking of the treatment of diarrhoea, Dr. Bartley had

spoken chiefly of the medicinal and dietetic, whereas he (Dr. Walker) placed the hygienic first. He had seen, for instance, in the city as well as at the sea-shore, severe forms of diarrhoea relieved by keeping the children out of doors, in the air but protected from the sun. He believed that better results would be obtained if physicians paid more attention than was generally paid to the details of hygienic treatment, instead of cursorily passing them over or leaving them almost entirely to nurses.

As to the feeding in diarrhoeal troubles, from what he could learn from others and from his own experience, milk prepared in some way was the only reliable food, and all the patented baby-foods, and all the imitations of mother's milk, must give way to it; but what method of preparing milk could be adapted to all children had not yet been discovered, although he believed that observers were working in the right direction—i. e., 1, to keep the milk in as nearly as possible the condition it was in when taken from the cow, and 2, to prevent fermentative and putrefactive changes in the alimentary canal; and there was where the antiseptic treatment of Dr. Bartley was of value.

After a correspondence with Dr. Corson, of Conshohocken, Pa., the speaker had used, where he could, warm, undiluted cow's milk, even with babies suffering from diarrhoeal troubles, and had been much pleased with the results. He had seen cases where milk prepared with barley-water, and in various ways, could not be digested, and yet whole undiluted milk was readily digested. The pancreatizing of milk was a valuable step in the right direction. The importance of being explicit as to directions was seen, in certain instances, where the mother had been told to give barley-water in place of milk, but was not told when to discontinue the use of the barley and to return to milk. The children were in a starving, marasmic condition.

He had been interested in ascertaining whether homœopathy was particularly "good for children with diarrhoeas," and had had abundant opportunities for observing the effects of homœopathic remedies, but had failed to find that they were any more efficacious than, if so generally as, those of the "old school." After all, it was the difference in the practitioners rather than in the medicines of the "schools" that gave different results.

As to the medicinal treatment, though he considered it of the least importance, yet it was important. The medicinal agents might be classified as follows: 1. Artificial digestives—pepsin, pancreatin, etc. 2. Medicines that removed or allayed irritation, viz., castor-oil, bismuth, etc. 3. Nervines or sedatives. 4. What might be called physiological antidotes—ipecac, corrosive sublimate, etc. In his hands Dr. Goodell's colic mixture, with a small quantity of deodorized tincture of opium or fluid Dover's powder, had repeatedly served a good turn in quieting a fretful child, and so decreasing the number of discharges; but all children would not take it readily, any more than they would the bromides, chloral, lupulin, etc., and he would like to hear from those present what had been useful in their hands.

Rectal injections of cold water he had also found, at times, would accomplish the same ends.

As a clinical fact, he called attention to the inability at times, in cases of severe prostration, of inducing vomiting even by apomorphine, and to the result being attained by the subsequent hypodermic injection of ether, ammonia, or some other stimulant.

Several years ago Dr. Hutchins, of this Society, had read a paper on "The Use of Salicylates in the Treatment of Gastro-intestinal Diseases." From this he had been led to use a mixture of salicylic acid, prepared chalk, mucilage of gum arabic, and spearmint-water in diarrhoeas with excellent results. An objection to bismuth was the discoloration of the stools. As to astringents, the *Geranium maculatum* seemed better than kino

and catechu. Dr. Bartley's suggestions as to boro-glyceride and other emollient and antiseptic remedies were excellent.

In conclusion, Dr. Walker asked the pardon of the Society for the rambling character of his remarks, which the want of time for preparation had rendered necessary. What he had said gave his individual opinions, and should be so considered. What was needed was the systematic and combined work, on some definite plan, of a number of gentlemen. Then individual opinions by classification and comparison would be of value. For this end he would be willing to work at the Sea-side Home and in the city in conjunction with other workers.

Dr. READ, referring to Dr. Bartley's remarks upon starchy food, had understood the doctor to say that "under one year of age starchy food should never be given to infants." He would dissent most strongly from this opinion. The truth was that much error existed in the wholesale denunciation of starchy foods, which was so often seen, and this variety of food was held accountable for much damage with which it had nothing to do, or rather with which it would have had nothing to do had the food been given of a proper kind and quantity. There were many varieties of starch, and there was as much difference in regard to the digestibility of these various starches as there was about the digestibility of the different kinds of meat. Potato-starch was the most difficult, and barley-starch the easiest of digestion, and between these two lay a large number, of greater or less ease of digestion. Starch, in its various forms, comprised the larger portion of infant food, and to say, therefore, that this kind of food should not be given, was to deprive ourselves of the bulk of foods suitable for the infant. Under the age of two or three months, it was true, children had not the full digestive powers for starchy foods, but that they did digest them, even at this age, was a clinical fact familiar to any one who had seen a child brought up from birth on barley, granam, oat-meal crackers, etc. The digestive powers of the child in respect to starchy foods increased rapidly, till, at ten or eleven months of age, it equaled, at least in diastatic effect, that of the adult. The clinical fact was, that children were fed on starch; that to milk we were constantly obliged to add starch of some kind. The real point in this troublesome problem of the proper feeding of infants was, not the banishing of starch altogether, but its proper selection, proper preparation, and proper administration.

Dr. ARMOR had one or two suggestions to make on the etiology of the disease; for, until we more clearly comprehended questions of causation, our treatment must necessarily be more or less empirical and uncertain. He desired to direct attention specially to three factors which had certainly much to do in the production of these gastro-enteric troubles of children, namely: solar heat, softening of the mucous membrane, and the development of low micro-organisms in the gastro-intestinal tract. That the disease had some relation to high temperature of the atmosphere need not be discussed. It prevailed only during the hot summer months, and had, therefore, been well named "summer complaint of children." He desired to direct attention, however, more particularly to the fact that excessive and protracted heat tended, in some way, to the production of a kind of gelatinous softening of the mucous membrane. This had been frequently observed post mortem, due allowance being made in all such cases for post-mortem softening. It was much more marked in hot than in cold weather.

To this predisposition to softening of the mucous membrane, the result of long-continued heat, there was added a catarrhal state of the membrane, in which the stomach was flooded with alkaline mucus, which not only diluted the natural gastric secretion and thereby weakened the digestive power, but, as modern research had shown, furnished the most favorable

possible condition for the generation and development of low micro-organisms, which contributed to putrefactive and fermentative processes. Had we given sufficient attention to the effect of these low organisms on a mucous membrane softened by heat and bathed in a copious secretion of alkaline mucus? And, if we added to these another factor which was a most prolific source of gastro-intestinal troubles with children during the summer months—namely, over-feeding, or feeding with unwholesome food—we grouped together elements of causation that might have important bearings on the treatment of “summer complaints” of children. He would not take up the time of the Society in discussing points of treatment at present. Many valuable suggestions had been made in the paper just read. Rational therapeutics must, of course, always rest largely on observation of fact—on carefully conducted experimental observation at the bedside—but pathology might give us valuable suggestive hints by directing us in these lines of observation.

Dr. J. T. CONKLE spoke in reference to warm milk as a food for children with gastro-intestinal diseases, and indorsed it heartily. If that could be secured, he thought almost all other kinds of milk-food could be discarded. It was well known that cow's milk underwent at once a great change, and, when the fat globules began to rise, it was no longer milk. All the skill of the chemist could not force the cream back into the milk. He had had experience with several cases of children suffering from summer complaints who were unable to take *any kind* of food. In one case he had asked the parents to go to the country and purchase a cow, and keep it for the use of the baby. They did so. The cow was driven up every three hours during the day, and once at night, to be thoroughly milked. The milk, drawn into a cup taken from a can of warm water to preserve the animal heat, was taken undiluted, and readily digested. This plan of feeding was, of course, only practicable in a few cases, but it demonstrated the efficacy of milk—that is, milk in contrast with that which bore the name in this city.

Dr. BARTLEY acknowledged the justness of the criticism that there was too much in his paper. His object had been simply to bring the subject before the Society for discussion. His paper had been made up of a series of suggestions. It was not intended to discuss the whole subject, because it was too large for a single paper. He admitted that there were a good many suggestions in the paper that were mere suggestions. In regard to the use of warm milk, that, of course, ought to be at once dismissed. It was impracticable. Even if we had the cow in our back yard, we could not look after it so as to procure warm milk that would be perfectly wholesome. The so-called farm dairies that we had driven up to the doors every morning were certainly inviting if we were to go behind the scenes and see the way the milk was manufactured—cows in stables without ventilation, and filth abounding on every side. Such milk could not be very wholesome. Then, if we took the milk from the country and produced in a wholesome way and transported it to the city, with its constant jarring, that which was handled three times before it came to the city and three times after it reached here, jolting all the time, it was pretty well churned by the time it got to the child. Take such a sample of milk, place it under the microscope and compare it with a sample of fresh milk, and we should find that, whereas the fresh milk was almost transparent between the fat globules, the churned milk showed a conglomerated condition of the casein. The casein beginning to undergo coagulation in many cases, this condition of partial coagulation would be found: the fluid was not perfectly transparent as it should be between the fat globules. But this paper had not been written for the country; it was meant more for the city, and based upon practice as seen

in dispensaries. Of course, if we were dealing with children of wealthy parents, we could be more successful, but with the poor tenement-house population we must do the best we could. Now, in regard to the digestion of starch, the recommendations he had made were based upon experience, not upon chemical analysis. He had tried the matter to his heart's content. He had seen some of the cases of those gentlemen who had recommended barley-water, starch, and everything except some imitations of milk. He had seen children recover without medicine. In regard to barley-water, he would say that in ordinary barley-water there was not so much starch, but a great deal of extractive matter, which changed the question entirely, and, further, that in the majority of cases the roasted barley was used, and in that there was a considerable amount of dextrin. In regard to Dr. Walker's suggestion of the mixture of Dr. Hutchins, when Dr. Hutchins presented that paper he (Dr. Bartley) tried it in several cases. Dr. Read also tried it, and, after two or three fatal cases, both had stopped using it. The trouble was, there were so many varieties of diarrhoea that, if we devised a prescription for a certain kind of diarrhoea, somebody else would use it for another kind and without the success anticipated. It required a great deal of care to differentiate cases. Bismuth, he thought, would always be used. It was valuable not only for its soothing effect upon the mucous membrane, but as an antiseptic. It should be used in large quantities—ten, fifteen, or twenty grains; small doses did little or no good.

Z. T. EMERY, M. D., *Secretary.*

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting of June 18, 1884.

Two Cases of Intestinal Obstruction: one from Impacted Fæces; the other by Stricture due to Cancer, with Specimen.—Dr. GEORGE W. VOGLER read the following paper:

Modern writers usually enumerate the causes of intestinal obstruction as follows: 1. Congenital malformation. 2. Internal strangulation. 3. Intussusception or Invagination. 4. Constriction. 5. Compression. 6. Impaction of foreign bodies or intestinal concretions. 7. Impaction of faecal masses.

Upon looking through the statistics of intestinal obstructive diseases, certain striking facts are noticeable. It is difficult to estimate the comparative frequency of intestinal obstruction. It is by no means a very common affection, always dangerous, and in a very large proportion of cases resulting fatally. Statistics show that most forms of obstruction of the bowels are more often met with in the male than in the female subject, the exceptions being obstruction by gallstone or faecal matter; constrictions by peritoneal or other adhesions, and compression of the intestine by tumors or displaced viscera.

As regards age and the portion of the intestine involved:

Obstruction by gallstones always occurs late in life, and involves the jejunum and ileum. Intussusception may occur at all ages, especially during childhood, and is confined chiefly to the large intestine.

Stricture is a disease of adult life (of course always omitting congenital malformation), involving the large intestine; three fourths of the total number being below the middle of the transverse colon.

With these few introductory remarks, I will proceed at once to the reading of the notes of a case of intestinal obstruction by constriction due to cancer:

Mrs. Mary Müller, German, aged fifty-eight years, widow, was admitted, April 18th, into the ward of my friend and colleague, Dr. Adam Tran, at the German Hospital. For some six months previous to her admission she had been under almost constant treatment by physicians. She states that constipation was her chief symptom, for which all kinds

of purgative remedies and various procedures were used, with but little avail. She was anæmic, considerably emaciated, and very weak. The chief symptoms were obstinate constipation, great tympanites, severe pain, and almost incessant vomiting. The temperature and pulse were not much disturbed. A careful physical exploration of the abdomen, vagina, and rectum, elicited no sign of a tumor. A long œsophageal tube was readily passed into the bowel, even to the length of twenty-seven inches, according to the statement of the medical resident. In brief, it seemed that the case was one of a paresis of intestinal movement, due to some defect either in the intrinsic ganglia and nerves of the muscular intestinal coat, or through imperfection of the muscular tissue by degeneration, or both these causes combined. The treatment consisted in the use of purgative remedies and large watery and stimulating enemata, with comparatively no results; turpentine stupes, followed by hot flaxseed poultices, gave some ease. The introduction of a long œsophageal tube into the bowel and massage of the abdomen afforded much relief. So great was the tympanites shortly before her death that respiration was materially interfered with, necessitating the introduction of a small aspirating needle to afford temporary relief. She was fed with pancreatized milk by the bowel, and Cibil's beef extract and stimulants by the mouth. Death occurred April 29th, by asæthia.

Owing to the interest taken in the case during life, the following gentlemen were present at the post-mortem examination, by invitation of Dr. Trau: Dr. Formad, Dr. Dercum, Dr. F. H. Gross, Dr. Barton, Dr. Jones, Dr. Vogler, and the residents, Dr. Weed, Dr. Stabler, and Dr. Rehfs. The body was emaciated and abdomen greatly distended, the intestinal convolutions being plainly mapped out upon the abdominal wall. The distension of the intestines, particularly the colon, was simply enormous. Some adhesions were noted. At the lower part of the descending colon a constriction was seen. This part of the intestine was carefully removed, and, when subjected to the hydrostatic test, was found to be impervious to a downward current, but readily permitted the passage of an upward current.

On opening the specimen along the line of the mesenteric attachment, a valve-like scirrhus tumor was exposed, which readily accounted for the phenomena observed in life—viz.: 1. Ready introduction of fluids into the bowel by a fountain syringe, also a rectal tube. 2. Failure of the fluid to be voided after withdrawal of the tube. 3. An almost total absence of the natural passages from the bowel. The specimen, which I now pass around, is well worth a careful inspection, the lesion consisting of two valve-like scirrhous masses completely encircling the bowel, to which it is alone confined.

The other case of intestinal obstruction was due to impacted feces:

Mrs. F., aged sixty-four, a private patient, was afflicted for many years with habitual constipation, frequently going many days without an evacuation. She began to complain, some three weeks previous to my visit, of severe pain in the left lumbar and umbilical regions, and an impossibility to relieve the bowels by powerful purgatives. No other symptom of note had troubled her up to within a few days, but now she was suffering with some fever, pain, nausea, and exhaustion, and was passing some bloody mucus from the bowels. Careful examination of the abdomen and vagina revealed a large, hard, and irregular-shaped body or tumor, situated in the left lumbar region, painful to the touch, slightly movable, and entirely free from the womb and its appendages. The diagnosis was determined by the history, the absence of acute symptoms, physical examination, and the process of exclusion of other causes of obstruction. By this time her life was in great danger. The treatment consisted chiefly in the frequent use of large enemata of soap-water, castor-oil, turpentine, and laudanum. Small doses of calomel and ipecac were given by mouth. After two or three days, some small and hard pieces of fecal matter were passed for the first time, and a careful examination indicated the mass to have broken in two—one occupying the old position, the other the sigmoid flexure. She was vomiting at this time. The quantity of fecal matter that came away during the following week was enormous. At one sitting,

as many as twenty-seven large pieces of hard, dry fecal matter came away, and I give this merely as an illustration of the quantity passed at one time. Frequently it became necessary to unload the rectum by digging out the masses. At times bloody mucus came away. Of course, the pain was very great during these operations, and opium had to be resorted to. Gradually the swellings began to grow less, and finally disappeared. The patient was able to trace their slow movements along the intestines by the intense pain. Only after weeks of careful treatment did this patient fully recover her health, and, strange to say, with a radical cure of her habitual and long-standing constipation.

The Demand for Early Exploratory Trephining in Depressed Fractures of the Skull.—Dr. JOHN B. ROBERTS read the following paper:

In using the term trephining I apply it to all methods of removing portions of the cranial wall, whether by the trephine, saw, burr of the surgical engine, gouge, or cutting forceps.

From observation, experience, and considerable acquaintance with the literature of the subject, I am convinced that surgeons are induced to decline or postpone the operation of trephining because of a mistaken idea of its serious nature, and a misunderstanding of the reasons for its adoption.

The frequency with which successful trephining was done in past centuries without the benefit of our improved methods and instruments, and the infrequency of death or serious symptoms from the operation itself at the present day, convince me that, though a capital operation, it is not one having in it many elements of danger. That many deaths occur after trephining is admitted. Such fatal results must often occur, for injury to the skull-bones is usually and almost necessarily coincident with disturbance or actual lesion of the brain or its membranes. I believe that more deaths are attributable to non-performance or delay in resorting to the performance of trephining than to its adoption. It behooves those who greatly limit the application of the operation to prove, by citation of cases, that a fatal issue has been induced by the procedure itself in a sufficient number of instances to throw the operation into the class called dangerous. To merely show that many patients with serious skull injury recover without trephining is not sufficient.

Much controversy on this subject would be avoided if the advocates and the opponents of an extended use of trephining would clearly formulate their opinions as to the theory upon which the operation is performed. In my opinion, trephining should be regarded in the light of an exploratory rather than a therapeutic procedure. I incise the scalp in closed fractures of the skull, not because the incision cures, but because it tells me the condition of the bone, without which knowledge I am unable to treat the patient rationally. The uncertainty of the lesion is, in my opinion, more dangerous to health and life than the conversion of a closed into an open fracture of the skull, because the observation of the profession teaches that open cranial fractures do not resemble, in fatality, similar open fractures of long bones. In truth, I would be willing to make a closed fracture of the thigh or leg an open one, if it was otherwise impossible to replace fragments which were threatening life. If I but learn the character of the skull lesion, I am acquainted with surgical expedients that render restoration to health more probable than the complication due to the incision renders it improbable. Hence I am justified, nay, compelled, by my reason, to advocate exploratory incisions of the scalp in obscure injuries of the skull.

The same line of reasoning forces upon me the conclusion that I should trephine whenever the fracture, whether originally an open one or so made by my incision, presents the possibility of the inner table being detached and splintered more extensively than the outer. In other words, I should cut the scalp to see the condition of the outer table; I should cut the bone to see

the condition of the inner table, in every case where the risk of obscure knowledge is greater than the risk of divided scalp and perforated bone.

Many experimental fractures made in the dissecting-room, and observation of cases in the practice of myself and of others, teach me that extensive shattering of the inner table, with only a moderate amount of fracturing of the external table, is of frequent occurrence in other as well as in punctured fractures. I admit that the condition in the dead subject, with its shrunken brain, is different from that in the living; but there is much evidence of the same splintering to be found in the study of accidental and homicidal skull fractures. Punctured fractures have long been treated by early trephining, to avert encephalitis. For the same reason I recommend trephining in more diffused and less accentuated fractures. It is to prevent inflammatory sequences due to splinters forced into the membranes and brain, and to avert the consecutive occurrence of epilepsy and insanity, that the operation should be performed; not because of the fear that symptoms of compression of the brain may arise, nor because necrosis of detached portions of bone may occur.

I am not a believer in the pathology that teaches that the symptoms which we call "compression of the brain" are due to displacing pressure exerted on the brain substance. How can a slight or even a considerable depression of a limited area of bone produce much pressure upon the brain substance? How can the usually limited extravasation of blood under the seat of fracture fatally compress the brain, which is of firmer consistence than the blood itself? A rapidly acting heart, after violent exercise, will throw enough additional blood into the cerebral vessels to produce more intracranial pressure than the ordinary depressed fracture. The complexus of symptoms called compression of the brain may possibly be the result of a disturbance in the local capillary circulation of the membranes and subjacent nervous tissue; but I can not believe it to be due to compression or displacement of the brain itself. It is more probable that compression symptoms are the results of encephalitis, due to injury from spicules of the inner table, or to the irritation of intracranial bleeding.

So soon as the profession repudiates the idea that brain displacement is what causes compression symptoms, every surgeon will be convinced that early trephining is a proper exploratory procedure in order to determine what measures are demanded to avert encephalic inflammation.

"Compression of the brain," as seen after injury, should be translated "inflammation of the brain," and looked upon as probably due to unrelieved irritation of the brain periphery, from traumatic causes. Not until this is so understood will the discussion as to the utility of trephining in depressed fractures cease.

I repeat, then, that trephining is not a therapeutic but an exploratory operation; and, as such, is demanded with much greater frequency than is usually supposed. If it is to be employed for exploratory and diagnostic purposes, early recourse thereto needs no defense.

When about to use the trephine itself for perforating the skull, to allow elevation and extraction of fragments, the surgeon should select a small conical instrument; one not over three eighths of an inch in outside diameter at the cutting end is large enough. Those usually kept by the instrument-makers are too large. It is only necessary to bore an opening sufficiently large to admit the end of the elevator; hence a small trephine is always more proper than a large one, except in those comparatively rare cases where a large disc is to be removed over the line of an old depressed fracture. Recently, I visited the four principal instrument-makers of Philadelphia, and could

not find in stock any trephine as small as that which I recommend. The belief which has caused trephines to be made so large is founded on an erroneous theory.

In recent depressed fractures the trephine crown should be applied upon the solid bone, and should overlap the *least* depressed edge of the displaced fragment. This allows more ready elevation or extraction by means of the elevator, because the *most* depressed edge is very frequently beveled, with the inner table broken at a more distant spot, and is thereby wedged under the solid portion of the skull at that side. Elevation at the least depressed edge is effected more readily and with less danger to the brain from the manipulation.

To conclude, I assert that in all subcutaneous injuries of the head with possible existence of depressed fracture, an immediate exploratory incision should be made in the scalp. In all instances of depressed fracture with *possible* existence of splintering and spiculation of the inner table, an immediate exploratory trephining of the skull should be done.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Meeting of May 7, 1884.

On a New Method of recording the Motions of the Soft Palate.—DR. HARRISON ALLEN read a paper on this subject, illustrated with drawings of the apparatus employed, and with numerous graphic tracings.

When a straight rod was passed through the nose from before backward in the living subject as far as possible, it would be found to impinge against the roof of the naso-pharynx. In this position it was not influenced by any motions of the soft palate; but, if the end of the rod which remained without the nostril was raised so that the rod was brought in contact with the anterior border of the nostril, the pharyngeal end would lie in a position which would cause a decided motion to be transmitted to it when the soft palate was raised. He had for a long time relied upon this test to determine when an instrument thrust through the nose had reached the region of the naso-pharynx.

Having observed that the sensations upon the fingers when the rod was thus held in position varied according to the character of the sound of the voice, he had made a series of careful comparisons, which had led him to infer that the elevation of the soft palate was greater in the sounds of *ä* and *ë* than in the sounds of *i*, *ö*, and *ü*, or in any of the short vowel sounds. Substituting for the support of the fingers a flexible copper wire, one end of which was attached to the head-band in common use for the support of the laryngeal mirror, the wire itself being bent round the rod so as to maintain the apposition of the rod against the anterior border of the nostril, he had found that the motions of the palate caused a perceptible deviation of the free end of the rod. If, while the wire was thus supporting the rod, a rhinoscopic examination was made, the pharyngeal end of the rod was found projecting from the posterior nares into the naso-pharynx, at a point about midway between the roof and the upper surface of the relaxed soft palate. The rod being carefully adjusted so as to secure the best effects when the palate was raised, and the subject seated in front of the Ludwig kymographion, which had been previously prepared with carbon-covered paper, it had been ascertained that when the free end of the lever touched the cylinder, at a time when the latter was in motion from right to left and the soft palate was raised, a distinct tracing appeared upon the cylinder and the differences between the long and short sounds of the vowels were found to correlate with the curves made by the rod upon the kymographion.

When the instrument was in position and the palate was raised (as in the voluntary motion which constituted the first act of deglutition), a tracing was made, which, when analyzed, was found to be composed of a number of acute depressions interrupting a horizontal line, and which yielded for examination three distinct parts: 1, a long, concave, slightly undulating line, which represented the extent of downward deviation of the rod from its horizontal position; 2, a short vertical line, which represented the descent of the palate, and began at the point at which the curved line ended and terminated at the horizontal line; and, 3, the horizontal line itself, which represented the record made by the end of the rod when at rest upon the surface of the moving cylinder. It was evident that the number of the notch-like depressions would answer to as many acts of elevation as were recorded at a single trial. The differences in the depressions would be the differences in the acts of elevation themselves. The degree of elevation and the abruptness of the fall were constant; but the length of the curve would depend upon the time taken by the palate to reach its highest elevation and the time it was sustained in that position before it fell to the position of rest.

The outlines, as a rule, were assumed to be due to the upper surface of the soft palate striking the end of the rod as it lay within the naso-pharynx. But the rod might be pushed from right to left or from left to right in a horizontal direction by the contraction of the two levator palati muscles; for the elevation of the palate was dependent upon the force exerted by these muscles, and, if the rod was in the way of one of them, it would be pushed to the median side and to a point nearer the center of the naso-pharynx than it occupied prior to the time of contraction. If the rod was thrust through the right nostril, it would be moved from left to right; if it was thrust through the left nostril, it would be moved from right to left. These curves were best recorded by placing the kymographion-cylinder in a horizontal position.

In making the tracings in either of the positions, the head must be carefully supported. A dentist's head-rest answered an admirable purpose. If at any time it was found necessary to estimate the amount of variation in any curve due to the motion of the head, a piece of wire attached to the head-band might be made to touch the cylinder a short distance above the position of the index on the lever.

As it was desirable to have a name by which the instrument could be designated, he would propose for it the term *palate-myograph*. In an exact sense it furnished the basis upon which the motions of the levator palati muscles (and through these structures the motions of the soft palate as well) could be recorded, and hence was a *myographion* of a particular pair of muscles whose general function was already known.

Dr. Allen then gave an interesting summary of the methods employed by other observers, and an account of various facts that his own method had brought out. After this, he continued substantially as follows:

The fact that the soft palate was raised in the articulation of all articulate sounds, that it was raised in the acts of swallowing, of coughing, of hacking, could readily be demonstrated. The length of time that it remained elevated, and the duration of the time of ascent and descent, could also easily be ascertained. The palate was seen to be raised once only for some words, twice for others, and three times for others. The numbers of these motions were invariable within a narrow range of individual variation. The size of the curves, however, was not fixed, owing to the difficulty of always reaching precisely the same spot of the broad upper surface of the soft palate. But the curves, whether deep or shallow, held the same proportions one to another. By proper care in freeing the rod from contact

with the salpingo-palatal fold, and in placing the rod about the center of the palate, the exaggeration of the curve could be prevented in great measure. It was evident that variations in the size of the bulb at the pharyngeal end of the rod would cause corresponding variations in the size of the curves. Hence it was recommended to preserve the form and size of the bulb described, and to free it from mucus.

Even if the same spot could at all times be reached, would it be reasonable to expect the curves to have uniform values for the same sound in different individuals, or in the same individual at different times, or even in the same individual at different times in a single sitting? The soft palate was but partially under the control of the will, and this control varied in different persons. The palate, like other muscular structures, was subject to fatigue, or might act irregularly from prolonged contact with the metallic rod. Again, the personal element that entered into the variation in the transit of volitional impulses must be as appreciable in the case of the soft palate as in that of any other muscular apparatus in the economy.

On the whole, it might be said that the sources of inconstancy of the curves were not sufficient to invalidate the claim of accuracy for the method.

The palate-myograph might be of use in studying the mechanism of the soft palate in disease as well as in health. It was evident that in paralysis of the palate the motions would be absent, and that by this method a means of detection of this condition was available. It might probably prove of use in studying stammering, and in determining the degree of degeneration of the levator-palati muscles in progressive dry aural catarrh.

As the soft palate ascended, the oral surface became concave. This concavity was occupied by the convex dorsum of the tongue in some sounds, like the consonant quality, *kā*, *qu*, etc., but might be free from the tongue in other sounds, like that of *o*. The elevation of the palate was not the result of the pushing up of the relaxed velum by the lingual basi-dorsum, but of active elevation by means of its own muscles. The correlations of the tongue with the palate were, as a rule, notwithstanding, exact enough to warrant careful comparison of the two factors in the mechanism of speech.

The palate-myograph might be employed in the study of phonetics, together with the different forms of glossographs as an accessory, if the premises put forward were correct.

On the action of the palato-pharyngeal and zygomatic muscles little could be said here. He had made a number of observations with a long, curved rod passed through the nose, and had ascertained that the approximation of the two palato-pharyngei might be recorded, but the retention of the rod in this position was painful, excited a little bleeding, and soon threw the pharynx into an excited state.

The plan of holding the rod in any desired position by the flexible wire and head-band could be used in keeping instruments in position—such as the snare, the syringe, etc.—so that the head-band might be employed in removing growths from the naso-pharynx and the nose.

PHILADELPHIA CLINICAL SOCIETY.

Meeting of June 27, 1884.

The President, Dr. HENRY BEATES, JR., in the chair.

Traumatic Sciatica and its Relation to Hip Injuries.—Dr. G. BETTON MASSEY read a paper with this title, in which he gave the histories of six cases, in the majority of which the sciatica had been overlooked while attention was directed to a search for osseous injury. In the first case he was called in

consultation to see an aged gentleman who had fallen on an icy spot of pavement eleven days previously. In falling he struck heavily on the left hip, and it was with difficulty that he arose and walked home—a distance of four blocks and a half. His family doctor, a prominent physician and an expert diagnostician, when called in, searched diligently for fracture, but could find none, notwithstanding the evident helplessness of the limb and the attacks of excruciating pain that was made worse by movement. At the time he was called in the physician had about concluded that the pain must be imaginary. On examination, the absence of any kind of fracture was apparent. The patient could lift the limb but a few inches from the bed. He was suffering from continuous and severe pain, felt most at points corresponding to the sacro-iliac notch of the affected side, behind the head of the fibula, and behind the external malleolus. The pain was aggravated by any movement, but especially by flexion of the thigh and extension of the leg. It was clearly a case of sciatica caused by contusion of the nerve in falling. At the request of the medical attendant, the reader of the paper joined him in the care of the case and applied the continuous descending galvanic current to the affected nerve, ending each sitting with a series of muscle-contracting interruptions of the current, great gentleness being required at first to avoid aggravating the pain temporarily. Good effect was manifest after the first visit, and eleven applications sufficed to establish a complete cure, recent careful inspection failing to detect either awkwardness of gait or atrophy of the posterior muscles.

The second case was that of a German woman aged seventy-three. On the 15th of January, 1883, she fell on the ice, fracturing the neck of the femur outside the capsular ligament. After she had been totally neglected for two weeks, a member of the family asked the reader of the paper to take charge of the case. He found the limb an inch and a quarter shorter than its fellow and greatly everted. At the seat of injury the great trochanter was lost in an abundant deposit of callus. No crepitus could be found. Great pain existed throughout the distribution of the large sciatic nerve, being especially felt in the peroneal and posterior tibial branches. In view of the age of the patient and the attempt at union already made by unaided nature, it was deemed unwise to interfere with the broken bone, so remedial efforts were directed entirely toward the relief of the sciatica. A series of blisters was directed, chloroform injections were made, various stimulating and anodyne liniments were applied, together with the internal administration of opiates and sedatives, but he felt bound to say the case seemed to improve slowly without being affected by any of these remedies. Electricity was not used, as the patient lived too far away to make it possible to apply it with sufficient frequency, and the friends declined to have her removed to a hospital. The pain continued over a year in gradually decreasing severity, and, although the patient had now been able to walk with crutches for some months, there was much atrophy of the muscles supplied by this nerve.

The four remaining cases were selected from the large number of cases of sciatica treated by the writer at the electric clinics of the Orthopaedic Hospital and Infirmary for Nervous Diseases.

The third case was that of a healthy hod-carrier, who was sent from Dr. Wharton Sinkler's clinic November 16, 1881. Seven weeks before, while he was carrying his usual burden up a ladder, his right foot slipped on a stick and threw the thigh into extreme flexion. He immediately felt an acute pain at the point of emergence of the sciatic and following that nerve down the thigh into the peroneal region. It was sharp and pricking in character, and had remained continuously present since the accident, being worse at night. He was unable to walk more

than a block at a time, and presented a gait markedly characteristic of sciatica. No atrophy was found. He was placed upon the use of static electricity, positive sparks being drawn from the painful points and the course of the nerve. After the fifth application it was noted that he was much better; after the twelfth that he walked three miles to the hospital; and after the twenty-second he was discharged cured.

The fourth case was that of a carpenter, aged sixty-eight, who was sent from Dr. Sinkler's clinic September 29, 1880. A healthy man, eight months before admission he fell on the ice, striking the right hip. He was compelled to remain in bed six weeks, suffering from pain in the region of the small and great sciatics. His physician was uncertain whether fracture was present or not. On examination, the gluteal and flexor muscles of the right leg were found much atrophied. He complained of great pain in the course of the right sciatic to the knee, and also in the distribution of the external peroneal. At times he felt some pain in the left leg. He was ordered the constant galvanic current thrice weekly. After forty-two applications he was noted as entirely well.

The fifth case was that of a man, aged forty, who was sent from Dr. S. Weir Mitchell's clinic May 6, 1881. Four months before he had fallen and dislocated his right hip. This was reduced shortly afterward, and he remained in the hospital eleven weeks, during which time, and up to his appearance at the clinic, he suffered from much pain throughout the sciatic distribution of that side. There was considerable atrophy of the buttock and limb—a difference of one inch and a quarter being found six inches below the trochanters. He was placed upon five-grain doses of iodide of potassium, and the constant current was applied thrice weekly. After thirty-five applications of the battery, considerable quantities of the iodide having been taken, it was found that the pain had ceased, but that some atrophy remained.

The sixth case was that of a porter, aged thirty-nine, who was sent from Dr. Mitchell's clinic June 30, 1881. Fifteen months before, he had been crushed between a platform and a moving car, by which the pelvis had been fractured on the right side. At his first appearance at the clinic some crepitus was still present, and there was two inches shortening of the right leg. He complained of much pain in the region of the sciatic nerve of the right side, which was increased by motion and exercise. He had been blistered and was taking five-grain doses of the iodide of potassium when he was sent to the electrical clinic. After twelve applications of galvanism, with some benefit, the summer vacation compelled a discontinuance, and he did not reappear in the autumn.

The obvious conclusions to be drawn from these cases were stated as follows: 1. Surgeons called to cases of hip contusion or suspected fracture should not fail to search for evidences of injury to the delicate nervous structures here situated. 2. If such evidences of nerve injury were found, prompt and energetic measures of relief were indicated, the importance of which was emphasized by the complete and rapid recovery of the two patients who were treated early. 3. Of the four remaining patients, one was distinctly benefited and two cured by more or less long continued (one to five months) galvanic treatment. The fourth did not receive galvanic treatment, and the case was fully a year in duration.

Dr. E. E. MONTGOMERY inquired how many cells had been used in the treatment. He thought that, considering the usual obstinacy of the class to which the cases related belonged, due to the inflammation of the sheath of the nerve, the treatment had been satisfactory.

Dr. L. BREWER HALL related the details of a case similar to those described which had been caused in a lady by her falling

from a horse's back and alighting on her hips. The pelvis was fractured, and a long-continued sciatica supervened.

Dr. MASSEY, in closing the discussion, said that the number of cells used varied from twenty or thirty to fifty, the kind being the gravity cell, which, owing to great internal resistance and the nature of the elements used, did not furnish so much current from each cell as the zinc-and-carbon batteries charged with acid. The number used was largely regulated by the varying resistance of the skins of different individuals, some skins permitting a free flow of the current, while others presented an almost insurmountable obstacle. It was to be regretted that the inventors had not as yet presented us with an instrument that would conveniently inform the operators of the true amount of electricity passing at a given moment. An approximation, however, to accurate dosage might be made by including a galvanometer in the circuit, or even by observing the sensations of the patient. Since the date of these cases he had used the static form of electricity in many cases of ordinary sciatica, and found it, at times, equally efficacious with galvanism, as well as more convenient.

Peru Balsam in the Treatment of Fissured Nipples.—Dr. DEBOIS called attention to the value of this application for *fissured nipples*. The balsam should be applied about four times daily after nursing.

An Improved Clinical Microscope was presented by Dr. HALL, on behalf of the Committee on Microscopy. It combined all the features of a clinical with those of an ordinary table stand.

Miscellany.

THERAPEUTICAL NOTES.

Orthoxysulphite of Phenyl, also called sulpho-carbol, has lately been proposed by M. Laborde ("Progrès médical") as a substitute for carbolic acid. It is said not to be poisonous and to be much less odorous than carbolic acid, while it is equal to the latter as a preventive of putrefaction and fermentation.

The Bromides in the Treatment of Albuminuria.—The "Deutsche Medizinisch-Zeitung" gives a summary of an article on this subject by M. Gobillard, published in the "Union médicale du Nord-Est." That author has found that, in recent cases of albuminuria due to cold, the attack is cut short promptly by the bromide of potassium, and that the same is true of the albuminuria of diphtheria, that of scarlet fever, and even that of pregnancy, but in chronic cases, and in those associated with affections of the heart, only a transitory improvement is produced.

Permanent Pills of Permanganate of Potassium.—According to a correspondent of the "Deutsche Medizinisch-Zeitung," a Russian pharmacist has hit upon an expedient for preventing the change which the permanganate is prone to undergo when made into pills. The formula is as follows:

Vaseline.....	2 parts;
Paraffin,	
White wax, each.....	1 part;
White bole.....	3 parts.

The vaseline, the paraffin, and the wax are to be melted together, and when the mixture is cold the bole is to be added. The permanganate of potassium is to be reduced to a fine powder in another mortar, and then added to the mass. The pill-machine used should be of horn or of wood.

Salicylic Acid in the Treatment of Chanoroid.—H. von Hebra ("Wiener med. Presse"; "Centralbl. f. Chir.") recommends the application of salicylic acid to chanoroids as an abortive method of treatment. After cleansing the sore thoroughly with spiritus saponis alkalinus, and drying it, pure salicylic acid is dusted on to it, and a little cotton is laid over all, secured in place with a strip of adhesive plaster.

It is generally sufficient to change the dressing once a day, but in cases of a free discharge it should be renewed twice daily. In a case related, at the end of three days the surface of the sore had become covered with a moderately thick white crust. The use of the acid was then discontinued, and an emollient ointment was applied spread on linen. After the crust fell off, cicatrization took place in a few days. It is suggested that this treatment is likely to prove a preventive of buboes.

Uva Ursi in the Treatment of Gonorrhoea and Cystitis.—H. Paschke ("Wiener med. Presse"; "Centralbl. f. klin. Med."), having found arbutin to be of little if any service in the treatment of these affections, has had the opposite experience with a pulverulent extract of *Uva ursi*, which he gives in doses of fifteen grains several times a day, either alone or mixed with sugar of milk. It always acts promptly as a diuretic.

Beef Peptonoids.—This preparation has been made the subject of analysis by Professor Atfield, who reports that he found the following constituents in 100 parts:

Albuminoids (containing nitrogen 10.94).....	69.25
Fat.....	10.71
Sugar, including a trace of starch.....	9.50
Phosphates, equal to bone phosphate.....	3.01
Other mineral substances.....	2.61
Moisture.....	4.92

Professor Atfield adds: "The manufacturers of 'beef peptonoids' state that this food is composed of dry lean of beef, one third; the solids of milk, minus most of the fat, one third; the gluten of wheat, one third—the beef being partially digested or 'peptonized.' My analysis fully supports this statement; for I find present between 69 and 70 per cent. of albuminoids, that is, flesh-forming material (nitrogen 10.94); more than 20 per cent. of warmth-producing substance, nearly half of which is milk-sugar, and rather more than half fat; 3 per cent. of bone-forming phosphates; about 2 per cent. of other normal mineral matter, and about 5 per cent. of moisture. A sample of the constituent gluten submitted to me was practically pure, containing a mere trace of starch. Rather more than one fourth of the albuminoids, probably the 'peptonized' portion, was soluble; while practically the whole of the 'beef peptonoids' was readily soluble in peptonizing fluids, showing that it is easily and wholly digested when taken into the stomach. The flavor and odor of the preparation are excellent; its thorough state of dryness fits it for keeping any length of time in any climate. It is by far the most nutritious and concentrated food I have ever met with. Indeed, a palatable and assimilable and in every way acceptable article of food, containing nearly 70 per cent. of truly nutritive nitrogenous material partially peptonized, has never before, to my knowledge, been offered to the medical profession or to the public."

Dr. Oliver's Urinary Test-Papers.—We lately published a notice of Dr. George Oliver's little book on "Bedside Urine Testing," in which descriptions were given of handy ways of testing the urine for albumin and sugar. Our attention has recently been called to an exceedingly neat and convenient pocket-case, prepared by Messrs. Parke, Davis & Co., the manufacturing pharmacists, of Detroit, containing, within a small compass, a supply of Dr. Oliver's test-papers and specific-gravity beads, together with a graduated test-tube, a graduated drop-glass, and a little manual explaining the use of these various articles. The whole arrangement is very ingenious, and can not fail to be of great service in facilitating the examination of urine without unnecessary loss of time.

Activity in an Old Vaccine Crust.—A remarkable instance of the preservation of the activity of a vaccine crust is related in a recent issue of the "North Carolina Medical Journal." It seems that during the term of office of the Hon. Willis Alston, grandfather of Dr. Alston (as a Congressman from North Carolina from 1803 to 1826), Dr. James Smith, of Baltimore, was Director of the Vaccine Institution for the State of Maryland. He sent to Mr. Alston a package of vaccine, and it remained unopened until it fell into the hands of his grandson, Dr. Alston, in May, 1869. It was a crust imbedded in wax and inclosed in a wooden box. Dr. Alston vaccinated his servant with a part of the crust, "and in due time," he writes, "it took effect, leaving a well-defined scar."

Original Communications.

ON THE ÆTIOLOGY OF
PULMONARY PHTHISIS.*

By B. F. WESTBROOK, M. D.,

PHYSICIAN IN CHIEF TO THE DEPARTMENT OF DISEASES OF THE CHEST,
ST. MARY'S GENERAL HOSPITAL, BROOKLYN.

It is with some diffidence that I appear before an association of this character with a paper upon so hackneyed and, as some may think, so sterile a subject as the ætiology of phthisis pulmonalis; and more particularly so as I have no new facts to offer.

I am not even prepared to discuss, on the basis of my own knowledge, the latest and most important discovery in the pathology of this disease, viz., that of the *Bacillus tuberculosis*. The discovery by Koch of what appeared to be the specific germ of tubercular disease has put the pathology of the subject upon a new basis, and completely changed the drift of discussion. It has, it seems to me, so completely absorbed the attention of the medical world that other and important matters are in danger of being entirely lost sight of. Yet there are many important factors in the pathology of phthisis besides the *Bacillus tuberculosis*.

Granting, as it appears we must, that the immediate exciting cause of miliary tubercles is the invasion of the body by these organisms, we have still to consider what are the conditions which precede this invasion and render the tissues susceptible to it. The importance of examining carefully into the question of predisposition is evident, inasmuch as the seed can not ripen and bring forth its harvest of death unless it falls upon a soil favorable to its development.

On the other hand, the exciting cause of tuberculosis—being ever present and unavoidable, except, perhaps, in some few favored localities—has as yet mainly a scientific interest; though we may hope that in the future we may be able to oppose its inroads more successfully than at present.

In studying the conditions which may be antecedent to, and prepare the way for, the development of phthisis pulmonalis, it will be convenient to adopt some form of classification. They may be arranged as follows:

1. Those conditions which are found in the bodies of ordinary healthy people.

2. Abnormalities of anatomical structure. These are either the result of direct inheritance, or proceed from disturbance of health in the parents.

3. Conditions arising from imperfect development of the body after birth.

4. Acquired disease in the lymphatic glands or connective tissues leading to the formation of caseous foci. These are causes of tuberculosis proper.

5. Acquired diseases in the lungs leading to the formation of caseous matter or collections of decomposing pus.

6. Such conditions of life as favor the occurrence of struma and caseous pneumonias.

It may be allowed, though there is as yet no proof of it, that, by direct inoculation, a healthy human being may be rendered tuberculous. But I think it fair to assume that, in the vast majority of cases, some or many of the predisposing causes mentioned are in existence prior to the advent of active tubercularization.

The conditions which are found in the bodies of ordinary healthy individuals, and which favor, indirectly of course, the occurrence of this disease, exist in the structure of the lungs and thoracic walls.

In studying the anatomy of the lung, we find that the respiratory mucous membrane undergoes important modifications as it passes from the bronchial tubes into the bronchioles and alveolar structures. When the caliber of the tubes is reduced to a certain diameter, the mucous glands disappear, and the tenuous walls are lined by a single layer of epithelium.

In the alveolar passages, infundibula, and vesicles, the epithelium, which was columnar in form during fetal life, becomes flattened when respiratory dilatation is established, and forms a single layer of flat cells, lying directly upon the vessels and connective tissue of the alveolar septa, with no submucous layer and no mucous glands.

It is true that the epithelial cells have everywhere a glandular action, and separate something from the blood. But in this case the activity of the cells is in the direction of the excretion of gases, aqueous vapor, and, probably, certain effete organic substances from the blood in the pulmonary capillaries. It can not be said that mucus is secreted below the line at which the mucous glands cease to exist.

The physiology of respiration teaches us that the air contained in the bronchioles and alveoli is never bodily changed except when collapse and subsequent rehabilitation occur. In other words, these small cavities never contract sufficiently to entirely expel their contents. Nor can any act of coughing or other effort cause them to do this; so that, if any substances accumulate in them, they must either be liquefied and reabsorbed, or, if some moisture exists to favor movement, they may be slowly expelled piecemeal; or, should neither of these occur, they will remain, and either undergo some form of decomposition, usually the caseous metamorphosis, or organize into a new tissue. The absence of mucous glands to supply moisture and the obstacles to the expulsion of dry substances from the alveoli thus appear to be two very important conditions, resident in the normal structure of the lung, and indirectly favoring the establishment of caseous foci.

Besides these, there are certain circumstances affecting both the sanguineous and aerial circulation in the *apices*, and favoring the location of disease there.

The thorax is so constructed that the muscles of inspiration, acting upon both sides simultaneously, reduce the internal pressure upon all sides; for, while the muscles do not act directly upon the extreme apices, where the pleuræ project through the superior opening of the thorax, nor

* Read before the American Climatological Association, May 3, 1884.

upon the mediastinal surfaces, still, the cavity being a closed one, any change in pressure not too rapidly induced will be felt equally in all its parts.*

In this way the apices and mediastinal regions will expand equally with the other portions of the lung, and the air will be invited into them. During expiration, however, the conditions are different. The thoracic walls, which have been expanded by the traction of the inspiratory muscles, return to the expiratory position through the agency of three factors—viz., the elastic contractility of the lungs, the resilience of the chest-walls, and the upward pressure of the abdominal contents. It will be seen that only one of these forces—viz., the elasticity of the lungs—acts upon the extreme apex. In this locality the cavity is closed in by a strong fascia, attached to the scapuli and first rib. During inspiration, this fascia, if moved at all, must descend. In forcible inspiration, its *relative* descent is well marked.† During *expiration*, it either remains stationary, or ascends. With a forcible expiration, as in coughing, its ascent is considerable. It results from this that, while the other portions of the lung have three forces acting to favor the expulsion of air from the alveoli, in the apices there is no other force than the contractility of the lung itself, and this is somewhat counteracted by the ascent, or tendency to ascend, of the cervical fascia.

The ordinary conditions, then, are not favorable to the free ventilation of the apex. The pulmonary circulation can not be perfectly performed, save in the presence of free movements of expansion and contraction, and the circulation in the apex, where these are diminished, is, consequently, not so free as in the other portions of the lung. In addition to this, the force of gravity tends to diminish the amount of fluid in the apex. It is the constant observation of pathological anatomists that the apices are the dry and anæmic portions of the lungs. They are the ill-nourished portions. If, now, owing to an inherited peculiarity of structure, to vices of general nutrition, or to old age, the movements of the upper portion of the chest are still further restricted, or, what is more important, if the contractility of the lung is diminished, both air and blood will have but a feeble circulation, and should any other cause, as a chill, intervene, to determine the flow of blood to the lungs, the vascular paresis will be felt most at the weak apices, and the tendency to effusion will be the greatest there. But the inflammation will not be a sthenic, croupous one, as it is when the hyperæmia is more active. Venous engorgement will be in the ascendant, the hepatization slow in appearing and disappearing, and the infiltration and cell-accumulation in the connective tissue predominant.

Another element of importance in the effect of the normal structure of the body upon the tendency to phthisis is the effect of the expiratory muscles upon the thorax in the act of coughing. This can only be operative in cases in which disease has already started in the apex.

The muscles of expiration act mainly upon the lower

portion of the chest.* In the sudden and violent expiratory efforts of coughing, the lower and middle portions of the lungs are, as it were, violently compressed. The effect of this compression is, I believe, to force the air upward toward the trachea, with such power and in such volume that it can not find an immediate exit, but a portion of it will be driven into the bronchi of the upper lobe, in which the current will be reversed, the air returning toward the alveoli. Should the cause of the cough be an ordinary bronchitis, the result will be an emphysematous dilatation of the alveoli of the upper lobes, either temporary or permanent, according to the duration, etc., of the bronchitis.† If the cough results from a catarrhal process at the apex, it will be readily seen that this reversal of the current of air will tend to force the morbid products back into the air-sacs, and favor their retention and caseation. While fluids gravitate from the apex toward the base, dry residues and collections of cells, always difficult of expulsion from any portion of the alveolar structure, are retained here with especial tenacity. The influence of these normal peculiarities of structure in favoring the location of phthisical processes in the extreme apices of the lungs is of immense importance, and should never be lost sight of in discussing the pathology of consumption.

Abnormalities of anatomical structure are of very great ætiological importance, as to them is due the constitutional predisposition of those unfortunate persons who, by direct inheritance of similar peculiarities from their parents, or as a result of the operation of impaired conditions of life upon the latter, have come into the world with a tendency to pulmonary phthisis. Besides *anatomical*, I might have mentioned *physiological* peculiarities; but, without lingering over the question of the interdependence of structure and function, we may assume that the two go together, and that mention of the one implies the presence of the other. The most evident deviations from the normal standard are to be noted in the general structure and external appearance of the body. Certain subjects present the well-known appearance of the phthisical habit. Aretæus is quoted by Laennec‡ as drawing the following picture: "Extreme whiteness of the skin, bright-red color of the malar eminences, narrowness of the chest, whence arises the wing-like form of the scapulae, and the slenderness of the limbs and of the body, although such individuals have a certain degree of adipose and *embonpoint*."

This, as Laennec justly observes, indicates, particularly, the appearance of the hæmoptysical. The long thorax, with sharp epigastric angle and small muscles, is known to all clinical observers as of bad omen in regard to the impending development of phthisis. So also are the subjects of scrofulous habit recognizable by signs which it is not necessary to enumerate here. All these appearances indicate abnormalities of anatomical structure, favoring, more or less directly, the occurrence of phthisis. But, of late years, a new field of anatomical study has been opened by Pro-

* For a careful study of this subject of intra-thoracic pressure, see

† The author does not mean to be understood as affirming that this is the sole cause of emphysema.

‡ Laennec, "Treatise of Mediate Auscultation," etc., p. 312.

fessor Beneke, of Marburg.* This is no less than the collection of data for the determination of the question whether the peculiarities and anomalies of constitution are not dependent upon differences in size, weight, etc., of the internal organs. Already the study of anthropometry had, in the hands of Quetelet, Roberts, Bowditch, and others, given interesting and valuable results, so far as the external anatomy was concerned; but Beneke and Thoma,† taking their hint perhaps from Virchow's observations on the arterial system in chlorosis, have made extensive series of measurements and weighings, in order to establish the anatomical basis of individual differences and anomalies. As Beneke observes: "We can not comprehend the working of the human machine as a whole unless we possess a knowledge of the absolute and relative proportions of all the separate parts of it. . . . There can be no doubt that an organism with a large heart, capacious arteries, small lungs, and large liver, will work out an entirely different result from one of the same age with small heart, narrow arteries, large lungs, and small liver." The result of his observations in regard to phthisis, up to 1881, appears to be that the ordinary phthisical subjects with caseous pneumonias are distinguished by the possession of relatively small hearts, narrow arteries, large lungs, small livers, and short alimentary canals.

Thoma's observations, which have been conducted on a very extensive scale, and are concerned to a greater extent with the establishment of averages for normal structure, on the calculus of probabilities, show, in the field of pathology, a somewhat similar result.

The labors of these anatomists, while still too limited to give us accurate results, point, undoubtedly, to an anatomical structure, either directly transmitted or else inherited, as a result of unfavorable conditions of life on the part of the parents, underlying and standing in a causal relation to the phenomena of special constitutional diseases.

The conditions arising from imperfect development of the body after birth, and which render the subject vulnerable to the tubercular infection, or favor the development of the caseation which immediately precedes it, are numerous and difficult of classification. They are, in the first place, a state of low vitality. By this I mean a state in which the volume of blood is diminished, the body dwarfed in one way or another, the chylipoëtic system feeble in its functions, and the nervous system ill nourished and inadequate to the ordinary duties of life. The circulation and respiratory movements are weak, the intellect, though sometimes bright, of a low order, and the capacity for work limited. The lungs are poorly nourished, poorly ventilated, and liable to the catarrhal and interstitial forms of inflammation. Again, we meet with the scrofulous diathesis. This, though often inherited, is frequently acquired as a result of exposure to various devitalizing influences. I will not take up the time

of the Association with a discussion of the pathology of this protean disease, but simply allude to it as one of the dyscrasias which favor the formation of cheesy deposits and the diminished vital activity which invites the invasion of parasitic diseases. The exanthematous fevers seem to predispose to phthisis, through their tendency to inaugurate the strumous diathesis. Typhoid fever presents some curious analogies to tuberculosis, or else some cases have been confounded by those who have observed them. An interesting collection of such cases has been made by Dr. Creighton in his work on "Bovine Tuberculosis in Man." They are, at least, a most interesting pathological study.

During youth and in adult life numerous circumstances occur which either directly deprive the body of sufficient nourishment, cause an excess of consumption over alimentation, or induce diseases which interfere with primary or secondary assimilation. These circumstances, sometimes obscure, sometimes impossible of detection, lead to a condition of inanition or wasting of the body which does not, I believe, render it specifically liable to *tuberculosis*, but favors the occurrence of adynamic catarrhs, asthenic pneumonias, and other chronic inflammations. This wasting of the body, precedent to the active manifestations of phthisis, has attracted the notice of pathologists and clinical observers from the earliest times, and, owing to the obscurity of its origin, has been considered a part or stage of pulmonary consumption. There has been much speculation as to the nature of this profound disturbance of nutrition, and many are the theories in regard to it which have vexed the medical mind. Dr. Horace Dobell, in his work on "The True First Stage of Consumption," in 1867, and "On Loss of Weight, Blood-spitting, and Lung Disease," in 1879, has given this subject a most thorough and able discussion, bringing to bear upon the question many original ideas and observations. Dr. Dobell thinks that this wasting or inanition of the body prior to the development of pulmonary phthisis should be considered the first stage of the disease, though he admits the specific nature of the tubercular virus. It is, undoubtedly, the first link in the long chain of morbid physiological actions which has its beginning in a state of almost perfect health and its end in the total disintegration of the body; and the subject can not be properly discussed without admitting this as a very important element in many cases. On the other hand, in many cases the signs of pulmonary disease appear before any perceptible loss of weight is observed. The idea of Dobell and others, that pancreatic inefficiency is at the bottom of the mischief, is one which we can scarcely accept. The pancreas is an organ with the pathology of which, beyond the occurrence of certain inflammations and tumors, we are not well acquainted. My own impression is that, like the other salivary glands, its diseases are few and simple. We know, however, that in debilitated states, as anemia, nervous depression, and imperfect oxygenation, the digestive fluids are not normal in quantity or quality.

There is a condition of atonic dyspepsia. The food substances introduced into the stomach and not properly digested undergo decomposition, with the formation of fatty and other organic acids and products of the disintegration

* F. W. Beneke, "Die anatomischen Grundlagen der Constitutionen-anomalien," Marburg, 1876; "Constitution u. constitutionelles Krank-sein des Menschen," Marburg, 1881.

† R. Thoma, "Untersuchungen über die Grösse und das Gewicht der anatomischen Bestandtheile des menschlichen Körpers im gesunden u. im kranken Zustande," Leipzig, 1882.

of albuminoid compounds. These irritant bodies, by their action upon the digestive mucous membrane, engender a catarrh which still further interferes with the primary assimilation. In some instances where, as far as we can see, loss of weight continues in spite of the fact that the patient takes the usual quantity of food and digests it, there is probably a fault in the original construction of the body, such as is spoken of by Professor Benéke as existing in the bodies of the victims of caseous pneumonic phthisis, viz.: "A relatively small heart, a relatively narrow arterial vascular system, relatively large lungs, a relatively small liver, a relatively short small intestine."* This lack of equilibrium between the nutritive and respiratory systems would seem *a priori* sufficient to account for much of the wasting that is observed in these persons. The statement of Rokitsansky, quoted by Dr. Dobell, and, as the latter says, confirmed by Dr. C. Meymott Tidy,† that the blood in phthisis is in a state of hyperoxidation, is worthy of further investigation. The further circumstance that phthisical patients, in spite of the pulmonary implication, are not usually cyanotic, is of cognate importance. But, in whatever way the details of this pathology of nutrition may be settled, Dr. Dobell has certainly done a great service to the profession and to humanity by his recognition of the importance of the digestive inefficiency in phthisical persons, and by devising means for remedying the defect. The importance of looking after the primary assimilation in those who are suffering from inanition, either with or without phthisical complication, has been very strikingly illustrated by the experiments of Dr. Debove and others in super- and artificial alimentation.‡ The results of Debove, whose main reliance is on pulverized lean meat, compared with those of Dobell and others, if they prove anything, show that it is not a lack of any one alimentary principle that needs to be supplied in these cases, but that the need is for very easily digestible and assimilable foods, irrespective of the exact proportion of hydrocarbonaceous, albuminous, or other ingredients. The advocates of cod-liver oil and fats have, in their enthusiasm, overlooked the fact that the wasting in inanition, and particularly in phthisis, involves the muscles as well as the adipose tissue. It involves almost everything, the wasting process, however, showing itself variously in different organs. The liver, notably, shows its lack of nutrition in a molecular disintegration of its cells with the local production of fat.

The importance of this defective nutrition as a predisposing cause of phthisis can not be exaggerated. Though recognized long ago, and insisted upon, particularly by Dr. J. H. Bennet,* it is receiving more attention now than formerly, and better practical results have been obtained since our knowledge of the physiology of digestion has been turned to account in its treatment.

‡ A very interesting account of Dr. Debove's methods and results may be found in the "N. Y. Medical Journal," April 19, 1884, p. 429, by Dr. H. B. Millard.

* J. H. Bennet, Reynolds's "System of Medicine," vol. iii, p. 546, 1871: "On Pulmonary Consumption."

It will not be out of place to refer particularly to the general constitutional weakness that results from long confinement in-doors. Whether this depression is a result of the continual action of the "gloomy passions," as was thought by Laennec* to be the case with those who spend their lives in conventual seclusion, or whether it is not rather induced by lack of sunlight, ventilation, and the varying sense impressions of ordinary life, needs little discussion. That the mortality from phthisis among cloistered orders is very high is, I believe, true. These instances are only of scientific interest, inasmuch as prophylaxis is impossible.

The fourth class of pathological conditions that predispose to the development of phthisis, or, as we may now say, render the body susceptible to tubercular infection, are acquired diseases in the lymphatic glands or connective tissues, leading to the formation of caseous foci. These causes would give rise to the true tubercular variety of the disease.

This class requires little more than a simple notice, inasmuch as it is generally admitted that caseous collections, whether in the lymphatic glands, connective tissue, bones, joints, or elsewhere, are frequently followed by miliary tuberculosis; and that the latter is so seldom found, save in bodies where such caseous deposits also exist, that the former must be regarded as its direct or indirect cause.

Acquired disease in the lungs, leading to the formation of caseous matter, or collections of decomposing pus, is, of all causes, the most important in the etiology of phthisis pulmonalis. This statement will immediately raise the question whether I am not confusing the disease itself with a cause of the disease; and, further, admitting the anatomical distinction between caseous pneumonias and miliary tuberculosis, are they not but different forms of the same disease? There has been so much theorizing and hair-splitting in the discussion of these questions that it is with great timidity that I approach them. But, if the Association will bear with me for a few moments, I will endeavor to keep out of the deepest part of the mire and wade through as rapidly as possible. In the first place, I think that we should make a clear distinction between the simple occurrence of a pulmonary inflammation, leading to localized cheesy metamorphosis, and the general collection of morbid conditions which go to make up a case of what we all immediately recognize as pulmonary consumption. One is a local process, more or less extensive, which may become latent and never give rise to further trouble, or may even undergo resolution; the other is a constitutional dyscrasia, involving the most profound nutritive changes in the body at large, and can seldom give a better result than by having its course somewhat prolonged. I would not by this be understood as holding the doctrine that phthisis pulmonalis is a specific disease, analogous to the zymoses. There is, to my mind, no evidence of its specificity prior to the development of miliary tuberculosis. It may be proved hereafter that caseous metamorphosis is the result of specific infection, but I think it is not proved as yet. The doctrine of Virchow and Niemeyer, that caseous pneumonia and miliary tuberculosis are two different things, is not, so far

* *Loc. cit.*, p. 310.

as I can judge, overturned by the immortal discovery of Koch. What, then, is phthisis pulmonalis? Phthisis pulmonalis is a chronic, wasting disease of varying etiology and pathology, whose essential anatomical lesion is a destructive process in the lungs, and whose most prominent symptoms are emaciation, cough, hæmoptysis, fever, and colliquative discharges. The important points in the etiology are, first, conditions which affect the general nutrition of the body in such a way as to give a weak nutritive power and to disturb the proper equilibrium between the physiological actions of its different organs; second, inflammations of the pulmonary texture which lead to its destruction. In order to make my meaning clear, I may refer to our ordinary colloquial expressions. If we examine a patient who is emaciated, coughs, and perhaps has had hæmoptysis, but find no evidence of disease in the apices, we say "he is on the verge of phthisis"; he may recover, but he will probably go into consumption. What we mean is that the clinical picture is not yet complete, that one or more of the essential conditions are lacking, and the distinction is recognized as such an important one that we base our prognosis upon it. Another patient may give evidence of slight disease at the apex, but without marked emaciation or without fever, and we say the same thing—"He is in great danger of having phthisis." Such a patient may never develop the rest of the lesions. He may recover. Of course, some signs are more highly diagnostic than others—*e. g.*, hæmoptysis is more so than cough; night-sweats more so than emaciation; a peculiar appearance of the larynx more so than bronchitis. The apical catarrh and fever are the most important of all, but still they are only a part of the disease. And in this, as in other diseases, there may be great individual variations. This has undoubtedly been the cause of much of the confusion of thought that has existed in regard to the true nature of phthisis pulmonalis. It originated when diseases were regarded as entities, and before the advent of modern pathological physiology.

Tuberculosis is also a part of the vast majority of cases of phthisis, but is generally one of the late occurrences, hastening the fatal termination. In some cases it is an early phenomenon, and may, indeed, play the leading rôle in the morbid processes in the lung. It can not, however, in the great majority of cases, be called a cause of phthisis, inasmuch as it does not appear till after the disease is well established. Acute tuberculosis should be classed by itself among the specific infectious diseases.

Before leaving this part of my subject I wish to say that, in these remarks upon the definition and pathological character of phthisis pulmonalis, I have simply given what seems to me to be the state of the case at present. I am not advocating any pet theory, as I have none.

The inflammations referred to as leading to caseation and the accumulation of decomposing pus are chronic bronchitis and peribronchitis, resulting in bronchiectasis; chronic catarrhal or desquamative pneumonia; and acute pneumonia, in which the products of the inflammatory stage are of such a character, or so located, that reabsorption and expectoration can not occur. It is affirmed by some, particularly by Dr. Leaning, of New York, that pleuritic inflammations

are, by extension into the connective tissue of the lung, a frequent indirect cause of caseous metamorphosis. While I believe that the doctor overestimates the frequency of this occurrence, I am far from denying its possibility. It may be possible, also, though I know of no evidence bearing directly upon the question, that the retention and decomposition of pus in the ventricles of the larynx may afford a supply of irritative material which, being inhaled into the deeper passages, can set up chronic bronchitis, peribronchitis, and pneumonic processes.

It is not within the scope of this paper to discuss the pathological histology of the lesions referred to above, but a few observations may be allowed in explanation of the statements made. In regard to the chronic bronchitides and pneumonias further remark is unnecessary. The acute pneumonias, however, require a little further discussion, as there has been much contention in regard to their ætiological relations.

That acute pneumonia does occasionally terminate in phthisis pulmonalis will be granted by every clinical observer. When, however, we inquire whether this sequel is only observed in cases of catarrhal pneumonia, or whether it does not also follow the croupous form, we meet with conflicting views. The difficulty lies in distinguishing, ante mortem, between croupous and catarrhal pneumonia. Cases of catarrhal or desquamative pneumonia are occasionally met with which can not be diagnosed except by their subsequent history, or by post-mortem investigation. If any one should maintain, as Buhl* does, that the cases which terminate in this manner are all cases of desquamative pneumonia, it would be very hard to disprove it. The immense pathological and clinical experience of this observer entitles his opinions to the very greatest respect. And, indeed, it would appear, *a priori*, that the great majority of cases in which acute pneumonia terminates in phthisis are really instances of catarrhal, and not of croupous, inflammation. If we bear in mind that the catarrhal pneumonias are the adynamic pneumonias; that a more or less cachectic condition is necessary to the occurrence of caseation, at least to any extent; that the increased proliferation of epithelium and collection of cells in the alveolar septa are the conditions necessary to caseation; and that these do not occur in croupous pneumonia—we have already good reason for doubting the liability of the latter disease to eventuate in the lesions of phthisis. But when we remember the additional fact that post-mortem examinations show that croupous pneumonia occurs mainly in robust people, or in those devoid of any evidences of a cachectic state, while the catarrhal or desquamative type shows itself in those who are of weak and infirm constitution, the strength of Buhl's position appears still greater. Owing to the essential differences between the histology of phthisical lungs and of those affected by the croupous pneumonic process, it must be admitted that, supposing that a croupous pneumonia eventuates in a phthisical lesion, it must, in the transition, have altered its characters and assumed those of the desquamative form. The practical

* Buhl, "Mittheilungen aus der pathologischen Institute zu München."

lesson to be derived from these observations is that, inasmuch as it is not possible in all cases, during their early stages, to diagnose croupous from desquamative pneumonia, the latter stages of this disease should always be most carefully watched, with a view to counteracting any tendency to chronicity. It is especially important to repeat the physical exploration of the chest from time to time, so as to keep track of what is going on in the lung; for, in cases of chronic pneumonia, the general appearance of the patient will sometimes improve, and he may express himself as feeling quite well, when an examination of the chest shows that solidification of the lung is still present. I have seen patients who, several weeks after the beginning of a pneumonia, had marked dullness upon percussion, with bronchial breathing and bronchophony over the affected area, although they expressed themselves as feeling as well as ever, and, to superficial observation, appeared so.

This study of the predisposing causes of phthisis would be incomplete without some more particular reference to those conditions of life which have been alluded to as favoring the occurrence of struma and caseous pneumonias. They are the conditions which it is one of the main objects of this Association to investigate. If the true relationship of phthisis to scrofula were more clearly ascertained, an important advance would have been made in the study of our subject. It seems, however, that the conditions which favor scrofulosis also favor the development of phthisis. In the present state of geographical pathology it is difficult to make any positive statements, but we may say that, as a general rule, the two diseases go hand in hand. But to this there are some notable exceptions. For instance, in Sweden and Norway, where phthisis is rare, scrofula is said to be exceedingly common,* though in Iceland and the Faroe Islands the former† is almost unknown and the latter rare. In the elevated regions of South America, again, where phthisis is very uncommon, scrofula is said to prevail extensively.‡ The meaning of these facts, if they are facts, is not apparent. We should bear in mind that the observations collected by writers are made by men of varying qualifications; that some have different ideas of pathology from those entertained by others; and that, in the absence of post-mortem records, made by reliable anatomists, much confusion may arise.

It should also be remembered that many of the recorded observations are made by travelers whose only or chief source of information is the accounts obtained from those with whom they come in contact. It is true, however, that many of the conditions which would favor the increase of scrofula also favor the development of phthisis. Residence in damp and gloomy places, where excess of moisture and lack of sunlight combine to interfere with the normal physiology of the body, is a prolific source of the disease. Bad food, particularly such as taxes the digestive power without furnishing a full proportion of the stimulating nitrogenous elements, particularly if combined with the former circum-

stances, should be considered as a formidable enemy to the proper nutrition of the body. A. Vogel* doubts the ability of these causes to produce the tuberculous diathesis except in those who are constitutionally predisposed to it.

That overwork, particularly where it is carried on indoors and on a poor diet, is a very frequent cause of phthisis pulmonalis, will, I think, be admitted by any one who has had practical experience in our large cities. The difference in health between domestics who are actively employed in well-appointed households and factory girls confined all day in one position, almost, in close, dusty rooms, is so noticeable as to attract the attention of the most careless observer.

This, however, may be partially due to other causes. All kinds of dissipation may be reckoned as causes of this disease, unless, it may be, excessive, continual drinking by those who are not overworked and who are liberally fed. Such persons tend to excessive development of adipose tissue and blood, and to diseases of the abdominal viscera. If they die of pulmonary disease, it is usually of acute pneumonia. A frequent cause, which is particularly observable in the present age, when great masses of population are shifting their homes and passing from one country to another, where they meet with entirely new conditions, is the change of vital operations caused by such a transition. It is a matter of common observation, in our large eastern cities at least, that large numbers of the emigrants, but more particularly the children of emigrants, fall victims to this terrible malady. In my own observation, they have been mainly the children of Irish parents, born upon American soil; but it may be true of other nationalities. The Irish emigrants are more prone to remain in New York and Brooklyn than those of other nationalities are, so that we have a better opportunity to watch them. I have been told by my friend Dr. Newton, of Rutland County, Vermont, that the same holds true among the Welsh quarrymen, who are employed in the slate and marble industries of that State. The explanation of this peculiar tendency in the children of emigrants is, probably, to be explained by a comparison of the conditions of nutrition and respiration existing in the parent country with those prevalent here. An organism whose structure is, by heredity, adjusted to the climatic and dietetic conditions of the British Isles, and particularly to the farinaceous and fatty food of the Irish peasantry, is not calculated to maintain its vital equilibrium under the altered circumstances by which it is invested in the New World. While the fully developed adult may succeed in accommodating himself to it, it is not so easy for an infant to develop healthily under circumstances so entirely different from those under which its ancestors have lived for centuries. These great ethnic changes were appreciated, years ago, by Dr. Daniel Drake, who even prophesied that some pathological phenomena would result from them.† Another and equally important observation, if it is correct, is that the inhabitants of the Antilles and of the Polynesian

* A. Hirsch, "Handbuch der historisch-geographische Pathologie," Stuttgart, 1883, 2te Abth., p. 433.

† Daniel Drake, M. D., "On the Principal Diseases of the Interior Valley of North America," Cincinnati, 1850, p. 648.

Islands were free from phthisis before the advent of civilization among them. Though the evidence seems strong, we are almost inclined to doubt it; but, if it is true, it may indicate either one of two things. Since the specific infection of tuberculosis has been discovered, it may be asserted that the European settlers introduced the virus among the aborigines of the newly discovered countries. Or it may be said that the change in their mode of life has affected them very much as emigration would. "The transition from a nomadic or savage life to civilization," says Lombard, "is one of the most favorable circumstances for the development of phthisis."*

In regard to the special influence of climate upon the tendency to phthisis I will say but little, as others are to give it a more thorough treatment than is possible in such an essay as the present. What the essential element is which gives immunity it is difficult to determine, except in a general way. That elevation is very important there can be no doubt. It is generally admitted that elevated and dry regions are more or less exempt from the disease. Equability is certainly favorable to the longevity of those almost affected. Temperature is of less importance. But, while admitting this much, we must not forget that some low countries are free from it. It is said not to exist among the Kirghiz tribes who inhabit a region which lies below the level of the sea. It is also not found in some countries the climate of which is very changeable, as Iceland, the Faroe Islands, and some of the Hebrides.

Why it is that moist localities in New England should be infested by it while the islands referred to are almost, if not entirely, free from it, is worthy of investigation. Stress should be laid upon the fact that Iceland is of volcanic formation. Very slight vegetation is found upon it, and in the valleys, where there is more or less swamp, the ground, even in summer, is frozen a short distance below the surface. Then the inhabitants live largely upon a diet of animal food,† It is essentially a marine climate, and that is not unfavorable in its influence upon phthisis.

It is stated by Laennec‡ that in France phthisis is far less frequent upon the coast than in the interior. Probably the immunity of these people is due to the marine climate, absence of miasmatic emanations from the soil, and their animal diet. It would seem to throw some doubt upon the importance of moisture, simply as moisture, as an ætiological factor. This very short and imperfect reference to the climatic influences may serve one useful purpose. A careful scrutiny of the facts presented and alluded to will, it seems to me, lead us still farther toward the recognition of the importance of errors of general nutrition as ætiological factors in the history of pulmonary consumption.

As the fundamental sciences of anatomy and physiology, both normal and pathological, are more fully investigated, new light will be thrown upon this subject, and it is to be hoped that, at no distant day, our knowledge may lead to the solution of many of the problems which now baffle our most determined efforts.

A CASE OF PARALYSIS OF THE LEFT VOCAL BAND

IN EXTREME ABDUCTION,
FOLLOWING AN INCISED WOUND IN THE NECK.*

By J. SOLIS-COHEN, M. D.,
PHILADELPHIA.

THE unique case here reported appeared at the Laryngoscopic Department of Jefferson Medical College Hospital in November, 1883, and was brought to my attention by Dr. Louis Jurist, one of the chiefs of clinic in that department. Shortly thereafter the patient became an inmate of the State Hospital for the Insane at Norristown, Pa., at which institution my friend Dr. Chase, the superintendent, has kindly afforded me every opportunity for examining this interesting larynx.

A. L., aged thirty-three, a drug clerk of Bohemian proclivities, and a slave to morphine, states that, while under the influence of liquor, on a lonely road a few miles from Omaha, in June, 1883, he was attacked by thieves, who threw him down and cut his throat. Within less than half a minute after being cut, and in the very act of crying for help, his voice gave out. The aphonia has been permanent.

Upon laryngoscopic inspection, the left vocal band is seen fixed in extreme abduction. The movements of the right band are normal in inspiration (Fig. 1) and expiration (Fig. 2), and

FIG. 1.—In forced inspiration.

FIG. 2.—In expiration.

that band passes the median line on attempted phonation (Fig. 3), as shown in the excellent drawings made for me by Mr. Max Stern, of Philadelphia, an undergraduate of Jefferson Medical College.

In forced inspiration the right vocal band recedes toward the side of the larynx, but no farther back than the fixed position of the left band, the shape of the glottis, indeed, apparently indicating that the voluntary abduction on the uninjured side is not quite so great as the permanent abduction on the impaired side (see Fig. 1). In strong attempts at phonation, not only does the right vocal band pass beyond the middle line, but the

FIG. 3.—In attempted phonation.

force of the expiratory blast of air throws the middle portion of the paralyzed vocal band upward (see Fig. 3), and sets it into

* Read before the American Laryngological Association, May 12, 1884.

a mechanical vibration, which yields a rough tone, but a tone in no wise phonic in the true vocal sense of that term.

It is a matter of regret to me that several of the members of the Association who have passed through Philadelphia did not avail themselves of an opportunity tendered them of examining this interesting case, inasmuch as it has not been feasible for me to have the patient brought here for inspection.

The paralysis seems due to lesion of the pneumogastric nerve in the wound of the neck, which, as may be seen from the plaster cast herewith presented, has been quite an extensive one. The sterno-cleido-mastoid muscle has been severed, and there is no trace of pulsation along the course of the carotid artery, or in its vicinity. The patient declares that the carotid artery was tied by the surgeon called to his assistance, but I have been unable, in a correspondence instituted for the purpose, to find any surgeon, in the neighborhood where the lesion is said to have occurred, who has any cognizance of the case. The statements of the patient are not to be relied on, and the injury probably took place in some other locality.

The incised wound in the neck, declared to have been homicidal, was evidently suicidal, as can be recognized in the cast before us. It resembles in its configuration the usual suicidal wound as I have seen it in a number of unquestionable cases.

The knife was evidently applied from behind forward. Starting quite superficially, the cut soon became quite deep, reaching its greatest depth in the carotid region, and then, becoming gradually more superficial, barely penetrated the skin for the last inch of its course. Described from before backward, the cicatrix extends anteriorly a little to the right side of the thyroid cartilage, about half an inch above the crico-thyroid membrane, crosses the larynx horizontally, and then traverses the entire left side of the neck, dropping an inch and a half in its course to a point behind the posterior margin of the sterno-cleido-mastoid muscle. The whole cicatrix is four inches and a half in length, and about one inch in width at its broadest portion. It is broadest in the region just posterior to the normal posterior margin of the divided and retracted sterno-cleido-mastoid muscle, where it has a gashed appearance, as though several cuts had preceded the main one. Two inches below the mastoid process of the temporal bone is a marked protuberance formed by the retracted upper segment of the sterno-cleido-mastoid muscle.

DISCUSSION.

Dr. KNIGHT—I think we ought to take evidence of this kind with much care. Why could not this have been a case of injury simply of one of the adductors? Why is it necessary to suppose that a portion of the nerve had been injured? It seems to me almost impossible, in the absence of a post-mortem examination, to gain much positive information from this case. There are so many disturbing elements in studying the question of the function of the recurrent laryngeal nerve that it is difficult to draw positive conclusions from cases of this kind.

Dr. LEFFERTS.—It needs, Mr. President, a very expert eye to diagnose between extreme abduction and cadaveric position of the vocal cord, which also would have taken place had the recurrent nerve been severed. Of course, I accept willingly the

testimony of an expert like Dr. Cohen, but, as stated, it is very difficult to differentiate between extreme abduction, the condition which Dr. Cohen describes in his case, and the cadaveric position. I once reported the case of a woman whose larynx was wounded by a pair of shears in the hands of her husband. The right recurrent laryngeal nerve was evidently severed. She endeavored to call out at the time of the injury, but found herself practically voiceless. At first the aphonia was nearly absolute, and remained in less marked degree ever afterward.

Examination of the larynx showed the cord in the cadaveric position, although the question was raised whether it was not simply in a state of abduction. It seems to me that the case was similar to the one under Dr. Cohen's observation.

Dr. SEILER.—I do not think that the cadaveric position necessarily follows section of the recurrent laryngeal nerve. Experiments upon a criminal, made years ago by Weir Mitchell and another gentleman, demonstrated that when one nerve was cut there was paralysis, but not complete, of the muscle of the same side.

The PRESIDENT.—I have never been able to understand how, in a case of complete severance of the pneumogastric nerve, or of that portion of it supplying the larynx, the muscles supplied by it could retain any degree of power. With regard to the question of diagnosis between extreme abduction and laryngeal paralysis, of some fifty or sixty cases of laryngeal paralysis which have come under my observation, in all there has been retention of voice. In only one or two cases was there at first a change of the voice to the falsetto, and that in time disappeared. I should suppose that in extreme abduction there would be complete loss of the voice.

Dr. COHEN, in closing the discussion, said: It is all important, in judging of the case under discussion, to see the patient, and I therefore regret very much that the gentlemen did not accept my invitation, when passing through Philadelphia, to visit the asylum where the patient is confined. There certainly could have been no direct injury to the recurrent laryngeal nerve; if any of the nerve-fibers supplying the larynx have been cut, it must have been before their departure from the pneumogastric. If, as we know, the adductor fibers of the nerve supplying the vocal bands may first be affected in some instances, why should not the adductor fibers alone be affected in other instances? May there not be two sets of nerve-fibers, the adductor and the abductor, in this case the latter group being affected?

I recognize no difficulty whatever in distinguishing between the cadaveric position and that of extreme abduction. In the latter condition the position of the bands is the same as is seen in extreme inspiration.

A CASE OF POST-PARTUM SYNOVITIS.

By JOHN FERGUSON, M. D., L. R. C. P., TORONTO, CANADA,
DEMONSTRATOR OF ANATOMY, TORONTO SCHOOL OF MEDICINE.

The subject of the following account was delivered of her first child on the 22d of February. The woman was in her thirty-third year, was of slight figure and nervous temperament, and had been for years a great sufferer from dyspepsia. The labor was an extremely difficult one; the os uteri was very rigid, the pelvis deep and contracted in all its diameters, while the perineum was tense and unyielding:

About three weeks before her expected confinement she asked me to call and see her, as she wished me to attend her. At this

interview I noticed the hands a little swollen and hard, and the lower eyelids puffy. On inquiry, I found that she suffered a good deal from headaches, that there was some nausea, that there was at times giddiness, and that objects were seen floating before her eyes. On examining the urine, I found it to contain about ten per cent. of albumin by volume when heated in the test-tube. She was placed under treatment for this, and improved considerably by the time of her confinement.

The head entered the pelvis with the occiput directed exactly to the left. Instead, however, of rotating forward, it rotated backward, causing an occipito-posterior position. The probable cause for this change was, that the pubic bones on each side of the symphysis were depressed inward toward the pelvic cavity. This, of course, would tend to make the occiput glide backward to the sacrum, as the left depressed pubic bone would come into relation with the right occipito-parietal suture of the fetus, and guide the occiput backward.

I applied the forceps with the hope of being able to adjust the position. This I could not accomplish; and, as the head became firmly wedged in the contracted passage, it became necessary to get assistance. Dr. Bryce was sent for, and we had fully two hours' hard work before we could bring the head down. During the passage of the head the rigid perinæum gave way, clean through into the rectum.

When the delivery was over the patient was in a state of extreme exhaustion, and was allowed to rest for a short time. I returned and put in five deep sutures. The patient became feverish almost from the first. There never were any chills. On the third day her temperature had reached 105° F. There was marked delirium. On the evening of this day there was a medium severe attack of uræmic convulsions. I gave most stringent orders to keep the legs tied together. This was not so carefully attended to as I could have wished.

I must confess I felt a little afraid to use opiates with any degree of freedom to constipate the bowels, knowing the condition of the kidneys. Still, I did order moderate doses. In spite of this the bowels moved. Indeed, there was a temporary diarrhœa. Owing to the convulsions and the moving of the bowels, the sutures gave way, and whatever union had taken place was broken down.

The septic condition of the system, which was very great, as shown by the high temperature, weak, rapid pulse, sallow countenance, and extreme depression, was treated by large doses of quinine, alcoholic stimulation, nourishing diet, sponging to the entire surface, and utero-vaginal injections every four hours. These injections consisted alternately of hydrarg. perchlor., one in two thousand, and phenol, one in eighty.

From the septicæmia the patient made a good recovery, at least so far as one could judge. In about four weeks from the date of confinement she was allowed to be out of bed for a short time each day. There was at this time rapid improvement in her general appearance. The temperature was perfectly normal. There was no evidence of pelvic trouble, and only a very slight discharge, which was thoroughly free from any fetor.

In about two weeks from the date when the patient began to sit up, or six from the date of the labor, and when the strength had been sufficiently regained to permit of the greater part of the day being spent out of bed, a pain was felt and complained of, at one of my visits, in the left wrist. On examination, it was found to be tender, a little swollen, only very faintly reddened, and painful on motion. There had been no chill whatever. Certainly I did not like this new visitor, but, as I could not tell his true nature nor make out a full identity for him, nothing was done save applying a soothing embrocation and warmth. Soon, however, other joints became involved,

and the disease traveled from one to another, until all had been invaded with the exception of the right hip.

During the first three weeks of this joint affection there were many painful points on the skin of the lower extremities from the knees downward. These corresponded in every respect to those met with in erythema nodosum.

At no time during the course of the joint-inflammation was there any albumin in the urine, as shown by repeated examinations.

The secretion of the skin was never sour or acid in smell. There was rather a heavy, musty odor, but not sweet nor like that of newly-mown hay.

No abscess formed during the progress of the case. The swollen, reddened, and generally tender condition of the joints subsided in four or five days to a week. There were usually several attacks in the same joint.

From the date of the arthritic seizure until it began to subside there was a sallow hue in the skin, at times almost approaching to a very faint jaundice tint.

The pulse was weak, soft, and irregular, and ranged about 100 to 110. There were frequent palpitations. The temperature varied often, but was never high. It stood mostly a little above or a little below 101° F., and only once did I find it as high as 103° F. At no time were there chills, nor any irregular sensations that could justly be regarded as their analogue. There was considerable nausea, and occasionally vomiting of a bilious character, and on three different occasions an attack of diarrhœa, when the food was passed somewhat undigested. The stools could not at any time be said to be pale or clay-colored. The temperature remained slightly above the normal for about two weeks after the joint pains had subsided.

On two dates the skin of the scalp was excessively tender.

The patient never had had ague, nor had she lived in an ague locality. Now, if we ask the question, What was the true nature of this case? several answers present themselves for our choice: First, there is that of an ordinary attack of acute rheumatism. Now, I am inclined to rule this out. There was not that marked rise of temperature that we would expect in a case so severe as to involve so many joints. Then, again, the sweat had not the sour smell we find in these cases. The disease also appeared to have more of a synovial character than that of true acute rheumatism, and, finally, the temperature remained elevated for about two weeks after the joints became free from pain. On the other hand, the metastatic nature of the disease, the erythema nodosum, and, according to Buzzard, the tenderness of the scalp, point to its rheumatic nature.

Against its truly pyæmic character may be adduced the fact that at no time did there occur the formation of an abscess.

It seems to come more under that class of cases where the absorption of impurities gives rise to joint affections without the formation of pus. Barwell, in his work on the diseases of the joints, mentions that he has met with altogether four cases of post-partum synovitis; and, from his description, they pursued a course somewhat like my case. Some infection is taken up from the utero-vaginal tract, which acts injuriously on the joints, giving rise to a metastatic synovitis.

As to treatment, preparations of the willow were used, and without the least beneficial effects. This is quite in harmony with Longstreth's teaching] that, if the joint

trouble is septic, then these agents have no power. This would also point away from a rheumatic nature.

Quinine in five-grain, and potassium bicarbonate in thirty-grain doses, as advised by Garrod, were then given, after the other had been tried for three days. These doses were given every four hours. This mixture gave very great relief to the joint pains. When the alkali and quinine had been used for about three weeks, the stomach became irritable, and would no longer bear the treatment.

Barwell's treatment for these cases was then adopted with great advantage. This consists in giving about fifteen or twenty grains of sulpho-carbolate of sodium, with about two grains of quinine, in half an ounce of camphor-water. Although the temperature still remained a little above the normal, the whole condition of the patient was greatly benefited, the skin becoming clearer and the joints freer, and there were less exhausting perspirations, a better appetite, and no nausea at the medicine.

Once during this part of the treatment she was put on the use of iron, as recommended by Bartholow and Reynolds; but at once relapsed, and had to be placed again under antiseptic medication. From this time forward the progress was steady, though slow.

No local treatment was employed, as there was not the slightest evidence of any discharge from the genitalia.

A CASE OF

CAVERNOUS PAPILLOMA OF THE VOCAL BAND.*

By FRANKLIN H. HOOPER, M. D.,

BOSTON.

THE features of this case, which seem to me of sufficient interest to warrant its being reported, are: 1. That, histologically, the tumor differs from any recorded case of intra-laryngeal growth. 2. That, although the diagnosis of "cyst containing blood" was justifiable from the appearances on laryngoscopic examination, in the clinical aspects of the case there were notable differences from those instances of laryngeal cysts and angiomas with which we are familiar through the writings of Moure, Cervasato, Tobold, Fauvel, Elsberg, and others. 3. The rather unusual and unexpected, but happy, termination of the disease.

The patient was first seen by Dr. Knight, November 22d, 1882, at which time he refused to submit to any operative measures. Returning in the summer of 1883, at a moment when Dr. Knight was compelled to leave the city, he was referred to me for treatment. The history is as follows:

T. G. C., a clergyman, thirty-two years of age, of nervous, energetic temperament, has always enjoyed good health, with the exception of his present trouble, which began in September, 1882, from taking a severe cold, accompanied by hoarseness. The symptoms of the cold lasted about three weeks, but the hoarseness has remained to the present time (August 1, 1883), causing him so great annoyance and distress that he had about made up his mind that it would be necessary for him to abandon

his profession. Apart from the hoarseness, there has been no symptom referable to the larynx other than a disposition to continually "scrape" it, and it seemed as if, by an extra effort, he might remove the source of the trouble.

Examination with the laryngoscope revealed a small nodular, sessile growth, situated on the anterior third of the left vocal band, and projecting from its free edge. Its size may be compared to a No. 7 shot ($\frac{1}{8}$ inch in diameter). Its walls were smooth, of a pale-yellow color, and, when examined with the sunlight, the red color of the blood within could be distinctly seen through them. The situation and shape of the growth suggested that it might be classed under the head of "cystic tumor"; but its peculiar color, the impossibility of applying the probe test on account of its small size, and the general appearances, so unlike the descriptions of angiomas, rendered the diagnosis as to its real nature somewhat doubtful. It was surmised, however, that the primary cause had been either a dilated or perhaps a ruptured capillary, the blood becoming subsequently encapsuled.

At the patient's second visit Fauvel's forceps was passed into the larynx, and borne well against the left vocal band. No attempt was made to open the forceps while in the larynx, the object of the procedure being principally to test the patient's tolerance of the instrument, and with but the faintest hope that it might make some impression on the tumor. On removing the forceps, it was with considerable surprise to myself, as well as gratification to the patient, that the growth was seen floating in the tumbler of water in which the instrument had been placed. The hoarseness had disappeared, and the voice was immediately restored. The growth had been knocked off close to its attachment to the vocal band, and had luckily adhered to the end of the instrument, together with a certain quantity of mucus. The hæmorrhage was insignificant, amounting merely to a single drop of blood. The growth was firm to the touch, and retained its globular form. It was handed to Dr. W. W. Gannett, pathologist to the City Hospital, for examination, and the subjoined report and drawing of the microscopical appearances were kindly furnished by him.

CAVERNOUS PAPILLOMA.

"The above is a diagram of a section vertically through the tumor of the larynx, left a few days ago. The outer covering is a many-layered, flat epithelium, showing dentate cells. Next is a rather loose connective-tissue wall, forming on its outer portion a basis for the epithelial cells, and on its inner surface the lining of a rather irregular cavity, with projections from the wall into the cavity, these representing, probably, trabeculae which had been cut across. The cavity itself is filled with red-blood corpuscles. The wall has not the structure of a *cassell* proper, but is rather a cavernous tissue.

"My opinion is that it was a cavernous tissue from the start, and does not represent a dilated blood-vessel.

* Read before the American Laryngological Association, May 13, 1884.

"I do not remember to have seen such a tumor before, but should think the term *Cavernous Papilloma* justifiable."

(Signed) W. W. GANNETT.

The patient was advised to abstain from preaching, and to allow the larynx as complete rest as possible for at least one month, but no special treatment was directed to the seat of the growth, and the day following its removal he left the city for his home in a neighboring State. There has been no recurrence. In a letter received April 10, 1884, he writes, in answer to my question, that he has "held special meetings six weeks in succession, talked or preached every night, and throat as good as new."

The only recorded case which bears any resemblance histologically to the one under consideration is described by Fauvel* as a "papillary polyp, with very pronounced vascular dilatations, making it resemble an angioma," which rather meager account is all that is given of its minute structure.

Dr. Fauvel's patient was a man, twenty-eight years of age, who for two years had been troubled with a progressive hoarseness. The tumor, of the size of a pea, rounded and smooth, was situated on the free edge of the right vocal band, and had a broad attachment. It was of a peculiar blackish color. Many attempts were made to remove the growth, but with no result except to bruise it, as it would glide from between the blades of the forceps each time it was grasped. Dr. Fauvel suggests that the cavities which were filled with blood may perhaps be accounted for by these manipulations which forcibly compressed the tumor. It was finally removed by evulsion, the hæmorrhage being more than usually abundant. No recurrence took place.

DISCUSSION.

Dr. CARL SEILER.—I am very glad to have heard the history of this case, the more so because I have met with one similar in almost every detail. The tumor was an angioma, of small size, of dark-red color, situated on the upper surface of the right vocal band, and not projecting from the edge. The man was studying elocution, and only complained of slight hoarseness. After considerable difficulty I succeeded in nipping off the growth. On examination, it was found to be composed of cavernous tissue, constituting a true angioma. The cavernous structure was small as compared with the epithelial.

Book Notices.

Dr. G. Beck's *therapeutischer Almanach*. II Jahrgang, 1884.

Des Taschenbuches der neuesten Therapie III Bändchen, 2 Heft. Bern, Leipzig, und Stuttgart: J. Delp, 1884. Pp. 88. *Therapeutische Notizen der "Deutschen Medizinal-Zeitung."* 1880-1883. Herausgeber Dr. JULIUS GROSSER. Berlin: Verlag der "Deutschen Medizinal-Zeitung," 1884. Pp. iv+100-xxiv. Price, 1.50 M.

THE scope of these two little books is very much the same, and their contents in many cases identical.

Dr. Beck's "Almanach," a former issue of which we received last year, is an index and brief notice of all the items of

therapeutic interest contained in the issues for 1883 of the "Index Medicus," Schmidt's "Jahrbücher," Virchow and Hirsch's "Jahresbericht," the "Allgemeine medicinische Zeitung," the "Bulletin général de thérapeutique," the "Journal de médecine et de chirurgie pratiques," the "Moniteur thérapeutique," the "Therapeutic Gazette," the "Monatsschrift der Ohrenheilkunde," the "Centralblatt für Gynäkologie," the "Centralblatt für Chirurgie," and the "Centralblatt für Augenheilkunde."

Dr. Grosser's "Notizen," which is almost identical in plan, except that the articles are arranged alphabetically instead of topically, embraces references to all the articles of therapeutic value contained in the "Deutsche Medizinal-Zeitung" for the four years from 1880 to 1883, inclusive. Nevertheless, it contains less than twice as much matter as the other book, which comprises only one fourth the same time, and we miss from it many important notices which the other contains. We can scarcely, therefore, agree with the author's assertion: "Da die 'Deutsche Medizinal-Zeitung' Alles wichtige aus den therapeutischen Veröffentlichungen der Jahre 1880-1884 enthält, so werden die Notizen auch andere Kollegen nichts Wesentliches vermissen lassen." As completeness is the one attribute essential for an index, Dr. Beck's "Almanach" must be allowed the precedence over its rival. Both, doubtless, would be useful to any one making a speciality of the study of therapeutics, or to any one anxious to learn all that is written about any individual drug; and, to a certain limited extent, they will be serviceable to the general reader. But the latter, to our thinking, will derive much more benefit from an index of his own compiling, drawn from his own reading, than by taking his information at second hand from books like these.

BOOKS AND PAMPHLETS RECEIVED.

The Principles of Ventilation and Heating, and their Practical Application. By John S. Billings, M. D., LL. D. (Edinb.), Surgeon, U. S. Army. New York: The Sanitary Engineer, 1884. Pp. 216. [Price, \$3.]

Lehrbuch der Physiologie für akademische Vorlesungen und zum Selbststudium. Begründet von Rud. Wagner, fortgeführt von Otto Funke, neu herausgegeben von Dr. A. Gruenhagen, Professor der medicin. Physik an der Universität zu Königsberg i. Pr. Siebente, neu bearbeitete Auflage, mit etwa zweihundertundfünfzig in den Text eingedruckten Holzschnitten. Erste Lieferung. Hamburg u. Leipzig: Leopold Voss, 1884. Pp. 160.

Quarantine and Sanitary Operations of the Board of Health of the State of Louisiana during 1880, 1881, 1882, and 1883. By Joseph Jones, M. D. APPLETON & Co.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, JULY 26, 1884.

THE CATSKILL MEETINGS.

THE annual meetings of the American Otological Society and the American Ophthalmological Society, held in the Catskill Mountains last week, seem, so far as can be judged from the reports given in this issue of the journal, to have been quite up to the usual degree of success. It will be noticed that the papers read were for the most part of a casuistic character rather than such as to enter upon anything like a systematic study of broad questions in pathology or practice. This seems to be the tendency of specialties after they have emerged from the formative stage, so to speak, and have become more or less settled, and doubtless it must be accepted as a token that debatable matters of generalization have to a great extent been decided or conceded to be for the time being insusceptible of settlement, and as arguing a general agreement that further clinical study is the need of the times. It is not strange that this should be the case, particularly in a specialty so nearly an exact science as ophthalmology.

Although the president of each society was absent, both gatherings were fairly representative of the various sections of the country, and certainly a great amount of work was gone through with. It has been questioned, and with reason, we think, whether the national societies were quite doing justice to the profession at large in holding their annual meetings at places of summer resort, and it has been urged that by so doing the societies took a stand still further aloof from the general body of physicians than was the natural result of the special nature of their work. It seems to us that, as general propositions, these objections to rural places of meeting are practically unanswerable, and it is within our knowledge that not long ago they led one of our national societies to reject a proposal to hold a meeting at a watering-place. We fancy, however, that it is only to a very limited extent, if at all, that they hold true of societies concerned with the study of branches so sharply differentiated from the general practice of medicine as those of ophthalmology and otology. At all events, the place of holding the next meetings of these societies is still an open question, for the Ophthalmological Society voted to leave the matter to its secretary and treasurer, and the meeting of this society governs that of the other so far as regards time and place.

THE STATE BOARD OF HEALTH'S STATISTICAL NOMENCLATURE.

THE State Board of Health of New York has recently issued a document entitled "The Statistical Nomenclature of Causes

of Death," designed to facilitate uniformity in the certification of deaths, and thus add to the accuracy and the intelligibility of the vital statistics of the State. The list, which is intended for the guidance of local boards, registry officers, and the medical profession, is essentially an abridgment of the new issue, now in press, of the "Nomenclature of Diseases" prepared by the Royal College of Physicians, of London, and revised by that body in conjunction with representatives of the National Board of Health of this country—an abridgment made by the late Dr. Elisha Harris, who was the secretary of the State Board at the time of his death. An explanatory introduction, signed by Dr. Harris, precedes the list, and this introduction, we think, will be found interesting, both by reason of its embodying the mature reflections of a very experienced statistician on the features desirable in a list of this sort, and because it affords some insight into the character of the revision which the College of Physicians' "Nomenclature" has undergone.

So far as it is possible to judge from this partial list, we are inclined to think that the new edition of the work of the College of Physicians will be found to be a distinct improvement upon the old one. Retaining essentially the anatomical basis for the nomenclature and classification of diseases, it gives evidence of a more conservative policy in the matter of adopting names, either as class designations or for individual diseases, that tend to convey ideas of pathology or ætiology which are at all questionable. For example, the new arrangement classes most of the diseases formerly called "zymotic" under the non-committal term of "general diseases"—a change which is certainly in the direction of a scientific suspension of judgment. To the same purpose, the disease before named "simple cholera" now figures as "epidemic diarrhœa," and "cholera infantum" is to be entered as "diarrhœa," "entero-colitis," or "epidemic diarrhœa." In short, the tendency is toward definiteness of expression and the avoidance of doctrinal points; and this is a tendency which makes in favor of increased usefulness, for any attempt to teach pathology or ætiology in such a document is out of place and can only act as a clog upon the availability of the work in its proper sphere.

The abridged list gives the names of the individual diseases in English, Latin, French, and German. It does not appear whether or not the French and German equivalents are to be given in the new edition of the "Nomenclature" of the College of Physicians. No doubt their addition would be a desirable feature even for the use of British physicians, but among a population so composite as that of the State of New York it is almost a necessity, and, if it was made by Dr. Harris, it must be taken as another proof of his devotion to the accuracy of statistical registration, and of his carefulness, for, although we have noticed some minor slips, we must say that the lists of equivalents are in general exceptionally accurate. While it would be ungracious to make the few errors that we have noticed the subject of special criticism, we may express the hope that in future issues of the lists the French word *matrice* will not be treated as if it were masculine.

MINOR PARAGRAPHS.

THE ALLEGED FRAUDS IN THE MEDICAL DEPARTMENT OF THE NAVY.

For some weeks past, mention has been made in the newspapers on various occasions of certain alleged frauds in the Bureau of Medicine and Surgery of the Navy. The charges have seemed to implicate only the clerks, and consequently until now they have had no particular interest for the medical profession. Recently, however, that spotless patriot, the Secretary of the Navy, goaded on by an intimation from one of the candidates for the office of Vice-President that these alleged frauds pointed to the propriety of a closer scrutiny of the affairs of the navy, and to their administration by new hands, wrote a letter to the candidate in question, wherein, with characteristic chivalry, he sought to shift the whole burden of responsibility for the frauds from his own shoulders on to those of the former Surgeon-General of the navy, Dr. Wales. Now, when we bear in mind that Dr. Wales has not been formally charged with complicity in the frauds, least of all convicted thereof, the method adopted by Mr. Chandler of besmirching his reputation seems hardly likely to carry conviction to any fair-minded person.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 22, 1884:

DISEASES.	Week ending July 15.		Week ending July 22.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	3	0	3	1
Typhoid Fever	7	3	20	6
Scarlet Fever	45	7	51	16
Cerebro-spinal meningitis. . .	2	1	4	4
Measles	181	26	164	31
Diphtheria	29	13	27	17
Small-pox	0	0	1	0

Cholera has increased rather than shown any tendency to subside in Toulon and Marseilles during the past week, but the outbreak is still practically confined to those cities, although a few cases are said to have occurred in Paris, Lyons, and Vienna. It is quite possible that the cases reported to have occurred in those cities were not really cholera. Precautionary measures continue to be taken vigorously throughout Europe, and it is satisfactory to be able to record that the authorities in various countries are approaching a substantial agreement in regard to the means best suited to stay the course of the disease; on the one hand, the British seem less disposed to ignore the advantages of moderate quarantine, and, on the other hand, the people of the Continent are beginning to see the uselessness of cordons on land, and, we trust, not only the uselessness but the cruelty of shutting a lot of human beings up together in an improvised settlement, obstructing travel, and, worst of all, fumigating persons with burning sulphur. It is such misdirected zeal as dictates practices of this sort that does more than anything else to bring quarantine into undeserved contempt.

Yellow Fever is reported to be prevailing on the Isthmus of Panama to such an extent that, together with an epidemic of dysentery, it has filled the hospitals both of the city of Panama and of Aspinwall. The death of a child is said to have occurred from yellow fever in New Orleans on the 23d inst.

The Foot-and-Mouth Disease.—The cattle shippers of Montreal are reported to have asked the authorities at Ottawa

to take measures to provide for a rigid inspection of cattle taken over the border from our Western States, fearing, as they allege, the importation of the foot-and-mouth disease.

A Marine Sanitary Patrol has been provided for in the following order, issued by the Secretary of the Treasury, under date of July 19th:

"In view of the presence of an epidemic of cholera, the existence of yellow-fever, and the Oriental plague, abroad, the safety of the public health in this country demands the enforcement of rigid quarantine against the introduction of these diseases through vessels arriving at our ports. Therefore, in order to assist local authorities in the maintenance of quarantine as provided in Section 4,792, Revised Statutes, the unrepealed portion of the act of April 29, 1878, and recent appropriation acts authorizing the President to maintain quarantine at points of danger, the President has determined to establish, by means of the vessels of the Revenue Marine, a national patrol of the coast of the United States, so far as it may be practicable under existing law and consistent with the performance of the other duties confided to that Service.

"You are accordingly directed to cruise actively with the Revenue Steamer _____ under your command upon the outer lines of your cruising grounds, and to exercise especial vigilance in speaking all vessels arriving from foreign ports, directing your inquiries, first, as to the port from which the vessel hails, and, secondly, as to the health of those on board at the time of departure, during passage, and at the time of hailing; and should the information gained indicate a condition of contagion or infection in the vessel or crew, or that the vessel has left a port at which contagious or infectious diseases were prevailing, her master will be directed to proceed for examination to the outer quarantine station provided for her port of destination.

"The following regulations will be observed relative to the inspection of vessels:

"If a vessel be found with sickness on board, or in a foul condition, she will be directed to proceed to the quarantine station hereinbefore indicated, and the revenue-marine officer will immediately notify the proper quarantine officer. In such case no person will be permitted to board the vessel until the medical officers in charge of the quarantine shall have given the usual permit.

"Should the pilot or master of a vessel when hailed report cases of recent or present sickness on board, the revenue officer will not board, but will send her immediately to quarantine.

"Quarantine officers will be recognized as follows, viz.:

"Medical officers or acting assistant surgeons of the Marine-Hospital Service, in charge of Gulf, South Atlantic, or Cape Charles quarantines, or any officer of said Service, on duty at any port on the interior rivers or the Great Lakes; and all quarantine officers acting under proper State or local authority.

"Herewith is transmitted a list of the ports and places where contagious diseases exist at the date of this circular. This list will be amended from time to time and furnished by the Marine-Hospital Service for your information.

"Special regulations to aid local quarantine authorities will be promulgated hereafter, should occasion require."

Railway Sanitation in Illinois.—With its usual well-directed energy, the Illinois State Board of Health has set to work to remedy the evils incident to insanitary conditions connected with the construction and the working of railways. Under date of July 17th, the secretary of the board, Dr. John H. Rauch, sent the following circular to each of the companies doing business in the State:

"As will be seen by a reference to the resolution in the

inclosed circular, the board deems it important that preparation be made for the possible advent of cholera.

"It is desired, as one important step in the general sanitary movement already inaugurated, that all railway stations, depots, and the grounds surrounding the same, be put in the best attainable sanitary condition, with especial reference to water-closets and latrines; and to the character of the water-supply for the use of employees and passengers. The same supervision should also be extended to passenger cars in the points specified. Accumulations of stagnant water, or the flow and seepage of foul drainage, in the vicinity of human habitations, are always injurious to health; but during a cholera epidemic they are especially dangerous. So far as such conditions obtain as the result of embankments or road-beds, they should be remedied as speedily as possible.

"The preservation of the public health—whereby, among other things, interruption of travel and traffic may be prevented—is a matter in which common carriers and the general public have a community of interests and duties alike; and to which it usually only needs that attention be directed in order to secure ready and efficient co-operation."

Cheese Poisoning in Michigan.—We are indebted to the secretary of the Michigan State Board of Health, Dr. Henry B. Baker, for an account of the last quarterly meeting of the board, held at Lansing on the 8th of July, at which, among other matters of interest, the subject of cheese poisoning was reported upon. The secretary presented a report on four outbreaks during the months of May and June, at Middleville, Jerome, Jonesville, and Big Rapids. All of the persons who ate of the cheese in question, about one hundred and sixty-four in all, were taken sick with the same symptoms, viz, pain and a burning sensation in the stomach, intense vomiting and purging, feebleness of the pulse, coldness of the extremities, and a tendency to collapse. All finally recovered. The cheeses were ordinarily good-looking specimens, but, when they were cut or broken, a liquid oozed into the pores. In each case the cheese was made at a factory in Fruitridge, Lenawee County.

Dr. V. C. Vaughan also read a report on the subject. At the request of the secretary, he had visited the factory in Fruitridge, and had analyzed specimens of the cheese. Everything about the factory had appeared to be scrupulously clean, and nothing in the vats, the cans, or the surroundings offered an explanation of the cause of the poisoning. Analysis showed no arsenic, copper, lead, iron, or other mineral poison. When the cheese was cut or broken, a whitish liquid oozed into the pores, and in this liquid microscopic organisms were detected. The liquid was very strongly acid. For more than a hundred years, the report continued, the attention of the scientific world had been drawn to the subject of cheese poisoning by repeated outbreaks of this sort, both in this country and in Europe. Much had been written on the subject, and many investigations had been carried on, especially in Germany. By various observers the poisoning had been ascribed to diseased milk, decomposition, and the development of certain fatty acids, etc.; but we did not yet know what made the cheese poisonous. In regard to the cases under consideration, the maker of the cheese had stated that the cheese which had produced the bad results had all been made between the 26th of April and the 26th of May, in the same manner and with the same care as other lots which had given no cause for complaint. Good cheese was only very slightly acid, and was slow in reddening blue litmus paper, but the poisonous cheese was intensely acid, a freshly cut surface of it reddening litmus paper instantaneously. This test for poisonous cheese appeared to be practical, as the litmus paper could be applied by any grocer to a freshly cut surface of the

cheese. If it was instantly turned red by the liquid which oozed into the pores, the cheese was to be suspected of being poisonous. We are informed that Dr. Vaughan's report will be published in full in the next Annual Report of the board.

The Oriental Plague, according to a press dispatch from St. Petersburg, dated July 18th, has appeared at Khars, in Asiatic Russia, and at various stations in the Caucasus, whither it was brought from Persia. It is added that the sanitary cordon at Baku proved entirely inefficient, eight hundred deaths from the disease having taken place at Bedra during the month of May.

The Latest Micrococcus, according to the "*Deutsche Medizinische Zeitung*," may be supposed to be the mysterious article advertised in the "*Berliner klinische Wochenschrift*" under the title of "*Residuen von rheumatischem Akutis*." The "*Zeitung*" expresses its joy that this new micrococcus has been dragged into the light of day, and wonders what sort of vehicle it will show itself to be.

The "Pacific Medical and Surgical Journal."—It is announced that the San Francisco "*Western Lancet*" is to be consolidated with the "*Journal*," and that the joint issue will be edited by the senior editor of the "*Journal*" and the editor of the "*Lancet*." An addition to the amount of reading matter is promised, together with other new features which, we have no doubt, will make this sterling journal still more valuable to the profession on the Pacific coast than it has been heretofore.

The American Ophthalmological Society.—At the recent annual meeting the following-named gentlemen were elected officers for the ensuing year: Dr. W. F. Norris, of Philadelphia, president; Dr. Hasket Derby, of Boston, vice-president; Dr. O. F. Wadsworth, of Boston, secretary and treasurer; Dr. J. S. Prout, of Brooklyn, corresponding secretary. Dr. Miles Standish, of Boston, Dr. John Van Dyne, of Syracuse, and Dr. S. O. Richey, of Washington, were elected to membership. The next meeting will be held on the third Wednesday of July, 1885, at some place to be selected by the secretary.

The Vienna General Hospital.—The "*Medical Times and Gazette*" announces that the one hundredth anniversary of the hospital will be celebrated on the 15th of August. The same journal states that Professor Auspitz has been appointed to succeed Professor Zeissl as director of the venereal wards.

The Summer Surgical Course at Kiel, as we learn from the "*Medical Times and Gazette*," was opened with an address by Professor Esmarch, who concluded by calling for three cheers for the Nestor of German surgery, von Langenbeck. On the same occasion he unveiled a bust of that surgeon and one of Stromeyer.

The Albany Hospital, as we learn from the "*Medical Annals*," of that city, is now provided with an ambulance which is described as very well appointed. The ambulance is to be kept in a livery-stable in State Street, subject to call by telephone or otherwise.

The Diffusion of Homœopathy.—The "*Gazzetta degli Ospitali*" quotes from another journal a statement to the effect that there are 403 homœopathic physicians in France, 244 in England, 94 in Spain, 26 in Belgium, 7 in Holland, 34 in Switzerland, 141 in Italy, 12 in Scandinavia, 67 in Russia, 47 in Portugal, 4 in Germany, 4 in Asia, 6 in Africa, and 1,612 in America.

The Contamination of "Soda Water" with copper salts and compounds of lead, derived from the faucets of the appa-

ratus from which the liquid is drawn in the shops, has lately been made the subject of investigation by the boards of health of New York and Brooklyn, in consequence of which the boards recommend the use of glass faucets instead.

The Italian Ophthalmological Association, according to the "Gazzetta degli Ospitali," will hold its meeting this year at Turin instead of at Palermo, in order that advantage may be taken of the large attendance expected at the National Exposition.

A Medical Prince.—The "Progrès médical" learns that Prince Ludwig Ferdinand, of Bavaria, wrote his inaugural thesis on the anatomy of the tongue, "A Study in Comparative Anatomy." There were fourteen sheets of text and one hundred and four chromo-lithographs.

Reported Suicide of a Physician.—Dr. William M. Dorrán, of Mount Vernon, N. Y., was found dead on Tuesday of this week, as the result of a pistol-shot wound of the head, supposed to have been suicidal. Dr. Dorrán was a native of Ireland, and a graduate of the medical department of the University of the City of New York. About a year ago he retired from practice, in consequence of failing health.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 13, 1884, to July 19, 1884:*

WRIGHT, J. P., Major and Surgeon. Assigned to duty as Post Surgeon, San Antonio, Texas. Par. 4, S. O. 87, Headquarters Department of Texas, July 14, 1884.

McELDERREY, HENRY, Captain and Assistant Surgeon. From Department of the Platte to Department of the East. Par. 12, S. O. 165, A. G. O., July 16, 1884.

EWEN, CLARENCE, Captain and Assistant Surgeon. Assigned to duty as Post Surgeon, Fort Sidney, Nebraska. Par. 8, S. O. 58, Headquarters Department of the Platte, July 11, 1884.

ELBREY, F. W., Captain and Assistant Surgeon. Leave of absence still further extended six months on surgeon's certificate of disability. Par. 6, S. O. 161, A. G. O., July 12, 1884.

WAKEMAN, WILLIAM J., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort D. A. Russell, Wyoming Territory, and assigned to duty as Post Surgeon, Fort Washakie, Wyoming Territory, relieving Assistant Surgeon Norton Strong. Par. 9, S. O. 58, Headquarters Department of the Platte, July 11, 1884.

Appointment.

EWING, CHARLES B., to be Assistant Surgeon, with the rank of First Lieutenant, July 5, 1884, vice Middleton, promoted. Memorandum, A. G. O., July 14, 1884.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the Navy during the week ending July 19, 1884:*

GIHON, A. L., Medical Director. Ordered as member of Board of Inspection.

PEBSONS, R. C., Passed Assistant Surgeon. Ordered to U. S. S. Saratoga.

SEIGFRIED, C. A., Passed Assistant Surgeon. Detached from U. S. S. Saratoga and ordered to Naval Hospital, Brooklyn.

SAYRE, T. S., Assistant Surgeon. Ordered to U. S. S. Independence.

Society Meetings for the Coming Week:

WEDNESDAY, July 30th: Auburn, N. Y., City Medical Association; Medical Society of the County of Gloucester, N. J.

OBITUARY NOTES.

Mr. Caesar Hawkins, of London.—A cable dispatch published on Tuesday announced the death of this well-known surgeon. For many years Mr. Hawkins was one of the surgeons to St. George's Hospital, and at the time of his death a consulting surgeon and a trustee of that institution. He was a frequent contributor to the English medical journals.

Dr. William Fruitnight.—This promising young physician died suddenly on Sunday, July 20th. He was a graduate of the Bellevue Hospital Medical College, in the class of 1880.

Proceedings of Societies.

CHICAGO MEDICAL SOCIETY.

Meeting of July 14, 1884.

The President, Dr. D. A. K. STEELE, in the chair.

Pyosalpinx treated by Volkmann's Method.—Dr. F. H. MARTIN read the history of a case as follows: Mrs. T., an American lady, twenty-seven years old, married, weighing 200 lbs., had had no children, but had had an abortion at the third month four years before coming under the reader's observation. She consulted him a year ago, supposing herself to be pregnant, as she had some of the symptoms of pregnancy, such as morning-sickness, enlargement of the breasts with pain, and increased size of the abdomen. Although she had menstruated regularly during the four months that she had considered herself pregnant, yet the flow was scanty. An ordinary digital examination was made, but no diagnosis was reached, and the patient was asked to call again, which she did in two months, when a second examination proved equally unsatisfactory. She was now seen in consultation by Dr. W. H. Byford, who, in consideration of her positive declaration that she felt the fetal movements, together with the other symptoms, was inclined to pronounce her pregnant, although her menses had continued to appear scantily every month. Five months subsequently she again consulted Dr. Martin, who, in conjunction with Dr. R. W. Bishop, made a very thorough bimanual examination with the patient anesthetized. The uterus, small and undeveloped, was found crowded close behind the symphysis pubis, and inseparable from a large, firm-walled tumor, about as large as the uterus at the fifth month of gestation, occupying Douglas's *cul-de-sac*, extending upward nearly to the umbilicus, and situated a little to the left of the median line. Owing to the patient's corpulence and the thickness of her abdominal wall, it seemed impossible to make an exact diagnosis. The uterus measured two inches and a half in length. The patient was again taken to Dr. Byford, who, after a careful examination, pronounced the tumor a fibroid of the uterus, but advised that an operation for its removal be delayed, although the patient was suffering greatly from the pressure on the bladder and rectum, from intense backache, and from other reflex manifestations. During the next two months her sufferings increased very decidedly, and she begged for the removal of the tumor or for some other radical measure of relief.

May 15th, with the assistance of Dr. R. W. Bishop, Dr. L. McArthur, Dr. E. L. Hollister, Dr. L. T. Potter, Dr. S. Black, Dr. T. H. Swayne, and Dr. E. J. Doering, Dr. Martin performed abdominal section, all necessary antiseptic precautions being observed. The incision made was eight inches in length, extending from very near the umbilicus to the symphysis pubis.

The omentum was firmly adherent to the tumor, the adhesions covering a space three or four inches in diameter; they were tied and carefully separated. Not until the omentum was liberated was the true nature of the tumor revealed; it proved to be the left Fallopian tube, excessively dilated, with thick, firm walls. It was so generally adherent to the surrounding parts that it might well have been taken for a fibroid or almost any other sort of solid tumor. Fluctuation was very indistinct, and only by introducing the needle of an aspirator was all doubt removed. On deeper examination, the mass was found to spring from the left horn of the uterus. To the outer side of the pelvis were the remains of the fimbriae, together with the ovary. The wall was muscular in character and very smooth. The operator intended to remove the tumor entire, clamping the small pedicle and attaching it to the wound, but this was found to be impracticable, so extensive were the adhesions. Besides those before mentioned, almost the whole upper surface of the mass was firmly adherent to the intestines, and the rectum was so involved as to appear almost as if it were a portion of the mass. Consequently, Volkmann's method of treating abscesses and similar tumors was resorted to, viz., stitching the wall to the edge of the abdominal wound and treating the cavity, after union, like that of an external abscess. The incision into the abdomen was closed, with the exception of the lower angle, where it was left open for about three inches. The tumor was stitched to the open edges of the wound in such manner that about two inches of its upper surface remained exposed. The wound was dressed antiseptically. On the fourth day firm adhesion was found to have taken place. A free incision was then made into the tumor and a double half-inch drainage-tube was inserted so as to reach to the bottom of the cavity. More than a quart of healthy pus was removed. The cavity was then thoroughly cleansed with a two-per-cent. solution of carbolic acid, and immediately after, to prevent any tendency to carbolic-acid poisoning, with a saturated solution of thymol. Night and morning the cavity was cleansed with a solution of corrosive sublimate, 1 to 3,000, and the external wound dressed with corrosive-sublimate gauze, 1 to 2,000. During the succeeding ten days the patient's condition was favorable, when the temperature suddenly rose to 102° F., and on the eleventh day it reached 103°-6°, the respiration being irregular and frequent and the pulse 160. Dr. C. Fenger saw the patient at this stage, and he concluded that the lining of the abscess was absorbing purulent matter, and that this was the cause of the constitutional disturbance. The opening into the abscess was enlarged with a blunt instrument, and its inner surface was scraped with a dull curette and cauterized with a twenty-per-cent. solution of chloride of zinc. A mural abscess was also found, and was opened and drained. After this the temperature became normal, the patient continued to improve, the abscess ceased to discharge, the wound closed, and perfect recovery ensued.

Dr. J. H. ETHERIDGE spoke of the great frequency of pyosalpinx, and of the common failure to diagnose it, and mentioned a method of examination for the purpose by means of the introduction of the entire hand into the vagina, the patient being anesthetized, as had been practiced by a physician at Denver. He then gave a verbal account of a case of pyosalpinx that had lately come under his observation, and showed the specimen, but did not state the particulars of the operation. The accumulation, which had existed for several months, had been the result of a perimetritis. The right ovary was free from adhesions, and was in a comparatively healthy condition. The right Fallopian tube was inflamed and enlarged. Its fimbriated extremity was so changed and enlarged by previous inflammation that the fimbriae were obliterated and the canal was absolutely occluded. The left ovary was

imbedded in an exudate that blended the broad ligament and the tube into one mass. The left Fallopian tube was inflamed and enlarged throughout its whole length, and its fimbriae were massed and indistinguishable, but its canal was patulous. The outer third of the tube was inseparably agglutinated to the upper surface of the ovary. It was impossible for the free end of the tube to be brought into contact with the ovary. There was a cyst-like accumulation of serum in the exudate within the broad ligament, the result of the perimetritis. There was, of course, irremediable sterility, but the chief source of danger lay in the patulous state of the abdominal end of the left tube, together with its inflammatory state, as the products of inflammation were constantly liable to escape into the surrounding parts and light up renewed attacks of acute inflammation. Nineteen months before, there had been an hæmatocoele, with menorrhagia, resulting in progressive anemia, emaciation, and debility. The entire removal of the uterine appendages seemed to be demanded, but death ensued in the course of a few days.

Dr. H. P. NEWMAN desired further information in regard to the methods employed for diagnosis in the early stages of the affection.

Dr. L. L. MCARTHUR had seen Volkmann's method carried out in three cases of abscess of the liver and in one case of abscess of the spleen, and all the patients had recovered.

Dr. L. T. POTTER asked whether the state of the neck of the uterus, in regard to length, was such as to warrant the introduction of a probe, which was liable to bring on abortion in case of pregnancy.

Dr. MARTIN closed the discussion, remarking that he had not discovered the exact nature of the swelling until he had opened the abdominal cavity, and aspirated the tube, over a year after the time he had first seen the patient. The great thickness of the abdominal wall had made palpation difficult, two or three examinations were made before the position of the uterus was discovered, and, since so many medical men had made a diagnosis of pregnancy, he had for a long time not felt justified in using the probe.

Fracture of the Clavicle and its Rational Treatment

was the title of a paper by Dr. S. W. WETMORE, who demonstrated two methods by the application of bandages to a student of medicine. He remarked that, although literature was replete with appliances for restoring and maintaining the fragments in position, for the last half-century surgeons had very closely followed many of the old masters; but the most simple, practicable, and satisfactory measures were to be credited to men of our own times. If the fracture was complete, the shoulder was depressed and drawn forward by the pectoral muscles, while the sternal fragment was salient and sometimes perforated the overlying tissues, so as to make the fracture compound, although this was rare. It was a peculiarity of the pectoralis major that its uppermost fibers were inserted lowest, and the clavicular fibers thus became the direct antagonists of the sterno-cleido-mastoid, so that the farther the humerus was carried backward the greater was the tension of those fibers and the more perfect the restoration of the fragments. The elbow double figure-of-8 bandage met all the requirements in an ordinary case of fracture in the middle third (the one under consideration), and this method, introduced many years ago by Dr. E. M. Moore, of Rochester, N. Y., was first described.

The reader had treated a number of cases with it during the past ten years, and without any unsatisfactory results. He heartily commended it to the profession. Its advantages were: 1. The apparatus was readily obtained. 2. It could be applied over the ordinary clothing. 3. It was adjusted easily when it became disarranged. 4. Any attendant could be instructed so as to keep it readily in place.

The next method described was that of Dr. Lewis A. Sayre, of New York. [As both this method and Dr. Moore's are well known to the profession, being described in the standard textbooks, we omit the detailed descriptions given by the reader.—*EDITOR.*] It would be obvious that the key to the successful management of this injury consisted in making the clavicular fibers of the great pectoral muscle tense and keeping them so during the period required for repair. No method could be successful if the humerus was allowed to maintain a vertical position. Sayre's method had some advantages: It was evidently the more secure, firm, and unyielding *at first* (very desirable qualities, particularly with children who could not be seen frequently), and the patient presented a more comely appearance when dressed. Its disadvantages were: The surgeon, and particularly the country practitioner, did not always have the plaster with him; in hot weather the plaster was apt to excoriate and become irksome and unpleasant; and, if sufficient traction was made on the humerus to make it useful as a lever, it necessarily became tedious to bear, and the patient tired of the constant strain. However, he did not feel qualified to criticise the method very closely. Both methods had been before the profession for several years, but he had been assured by a number of his friends that they were comparatively unknown; it was on this account that he had brought them forward.

Dr. R. W. BISHOP made brief mention of a case of double fracture of the clavicle that he had recently had under treatment, in which a three-cornered piece of the bone had been broken off, was turned edgewise under the skin, and could not be kept in position.

Dr. C. E. WEBSTER had visited Bellevue Hospital last year, and had been informed by an interne that Sayre's method was employed in most instances at first, especially if the fracture was dressed in the lecture-room, but that the plaster soon became loose and gave rise to excoriation, so that other appliances, not unlike those commonly seen, were subsequently made use of.

Dr. L. H. MONTGOMERY had treated a number of fractures of the clavicle, but none of them had been compound or comminuted. In all of them union had taken place, and the patients, so far as he knew, were as strong as before the accident, although in all but two of the cases a deformity was left. One was the case of a little boy with a so-called "green-stick" fracture, and no deformity resulted. The other was that of a young man who was willing to lie abed for three weeks if the speaker could promise him a perfect result. He lay on a hard mattress for nearly that length of time, with a dressing consisting of bandages and a bag of sand applied over the seat of fracture, and a perfect result followed. The speaker would commend this method, especially in the case of a lady. He asked Dr. Wetmore if the treatment by Moore's method would apply to oblique fractures as well as to those that had been referred to in the paper.

Dr. W. L. AXFORD thought deformity almost always resulted. To raise the outer and lower the inner fragment was the correct plan of treatment, and yet more or less deformity would result. He was skeptical in regard to methods which were said to give perfect results. He asked the reader of the paper if any of the cases he had treated by Moore's method had resulted in deformity.

The PRESIDENT had seen the case of comminuted fracture referred to by Dr. Bishop. What the reader of the paper had called Moore's method was the same as was known here as Isham's. It gave as good results as any, unless it were a plaster-of-Paris bandage. He had long since abandoned the adhesive-plaster method, and thought the let-alone plan was about

as good as any. Nature would bring about a good result, although it would be well to try to maintain apposition by a tight-fitting knit shirt.

Dr. A. B. STRONG thought the subclavius muscle had something to do with the deformity, for it was irritated and excited to contraction. He had never seen any dressing prevent deformity, and he thought the best plan was simply to put the arm in a sling or have the patient lie on a hard mattress.

Dr. W. H. CURTIS referred to the danger of producing constriction of the brachial artery if the plaster dressing was applied too tight or kept on too long.

Dr. WETMORE closed the discussion, and stated that he had treated a great many cases in children, in adult females, and in men during the past twenty-five years. In those cases treated by the method he had advocated most urgently there had been no deformity, although many of the patients had been strong, athletic men.

Rhinolithiasis, with the Report of a Case of probably Forty Years' Development.—Dr. JEFFERSON BETTMAN exhibited a specimen and read an elaborate paper on this subject, of which the following is an abstract: On account of its illustrating the features of this somewhat rare affection very well, the case was first related. The patient was a gentleman, forty-nine years old, who consulted the reader in June, 1883, for what he termed "chronic catarrh in the head," extending over a period of many years. Shortly before he consulted Dr. Bettman the annoying symptoms had become more aggravated. The usual discharge was so copious as to make the use of from four to six handkerchiefs necessary daily. Periodical attacks of hemi-crania, extending over the right orbital and temporal regions, also complicated the case. There was marked obstruction of the nasal respiration on the right side. The patient was a large, well-proportioned man, the picture of florid health. The nose appeared congested and slightly tumefied, and the borders of the nostrils were somewhat excoriated. The introduction of the nasal speculum occasioned violent attacks of sneezing. This exquisite over-sensibility of the mucous membrane quite precluded a thorough examination of the nares. There was moderate fetor of the expired breath, yet sufficient to be imparted to the nasal secretion; the latter was also viscid and slightly flocculent, and filled both nostrils; it required to be removed before a survey of the parts could be made. On illuminating the nares, a marked vascularity and thickening of the mucous membrane were noticeable. The tissues covering the inferior turbinated bones were so thickened as to encroach upon and nearly obliterate the respiratory channel. The mucous membrane covering the septum presented almost a fungous appearance, and both middle turbinated bones were so enlarged as to press upon the septum. The posterior part of the right nasal fossa was filled with an accumulation of creamy-looking discharge, and attempts at its removal by a well-directed stream of tepid water were futile. The nasal lumen was so narrowed and encroached upon by the hypertrophied turbinated bone and a co-existing deflection of the septum that it was with difficulty that a cotton-wrapped probe could be guided through the parts which were so sensitive. Palpation revealed the presence of a hard, grating substance occupying the floor of the right nasal fossa, which was supposed to be bone necrosed as a result of a dyscrasia. Thorough inquiries elicited negative replies in regard to that matter.

To allay the morbid sensibility of the parts, a detergent nasal lotion was advised for the time being. In two days' time this proved effectual, as the over-sensibility and tumefaction of the mucous membrane were markedly reduced. Under a strong illumination, the position of the foreign body was then defined, and it was found to be lying on the floor of the nasal fossa in

its posterior half, apparently impacted between the bony septum and the inferior turbinate bone. The exposed surface of the body was rough, uneven, and unyielding to the touch of the probe. To dislodge and remove it, a strong aural forceps, bent at a right angle, was used. Firm resistance was met with on traction being made. The fauces, too, were uncontrollably irritable, defeating all attempts at posterior rhinoscopy. The size of the body had undoubtedly been underestimated. Its removal *in toto* anteriorly was impossible, on account of the narrowness of passage. Attempts at removing it piecemeal were but partially successful after repeated trials. The feasibility of removing it through the naso-pharyngeal space presented itself. The patient having been cautioned not to take a deep breath or swallow during the manipulation, the operator guarded the faucal orifice and forced the foreign substance into the naso-pharyngeal space, from which in a moment the gentleman spat it out. It was darkish gray, almost black in color, conoidal in shape, and of a very disagreeable odor. Its weight, its firm consistence, and the pebble-like uniformity of its unexposed surfaces were sufficient to indicate its calcareous constitution. Irregular in shape, its contours conformed to those of the surrounding parts. Its median surface measured 1.5 cm. in length by 1.25 cm. in breadth. The inferior surface was 1.5 by 0.5 cm. The exact weight was a gramme and a half. Imbedded in the mass was a cherry-stone. The incidents of his childhood were vividly impressed upon the patient's memory, but he could not account for the presence of the cherry-stone. Free nasal respiration was fully restored, and great relief followed. Subsequently, however, a small mucous polyp was discovered high in the same nostril, covered and almost hidden by the middle turbinate bone. It was easily removed.

The literature of the subject of rhinolithiasis was then reviewed by the reader at great length. Störk averred that he had seen but one example of the affection. In many works on general surgery no mention of it was made. The term was first applied by Demarquay, and our French *confrères* had described the greater number of cases. Demarquay and Poinso had written *brochures* on the subject. The determining cause was the presence of a foreign body, which formed a nucleus for the deposition of lime salts. Nasal concretions had, however, developed independently, without being due to the presence of any extraneous substance. Congenital or acquired atresia and stenosis of the nasal lumen favored the retention and subsequent desiccation of nasal secretions, and furnished the nidus for a concretion. A gouty diathesis might also be a predisposing cause. Virchow had described a diathesis *ossifica*, which was an entirely different process, yet somewhat allied to the affection under consideration.

During an act of vomiting or retching, undigested particles of food, being forced through the naso-pharyngeal space and lodging in the posterior nares, might be the nidus. Barring this possibility in the case related, the concretion might be presumed to have been more than forty years in developing. Jacquemart had lately described a case in which the trouble had existed over twenty years. Multiple rhinoliths had been found in rare instances. The concentric arrangement of the constituents of these concretions and their chemical composition were next considered. The symptoms occasioned by their presence were frequently not marked, so that doubtless they were often overlooked, the rhinorrhœa being regarded and treated as due to a catarrhal congestion, which might often result in epistaxis. According to Billoth, the chronic vascularity induced a state of overnutrition and cellular activity in the surrounding tissues, favoring redundancy and neoplastic changes. Hemiorrania, or nervous headache, was a noteworthy symptom in many cases. According to Axmann, the latter

might be periodical, and be checked by the spontaneous expulsion of minute concretions, and Hack had added that other reflex neuroses might also be present. Posterior rhinoscopy occasionally was of practical service in this connection. In Jacquemart's case, already alluded to, he and more than ten consultants had made a previous diagnosis of osteo-sarcoma. A few cases were on record in which rhinoliths had been expelled spontaneously while they were very small. A stream of hot water, injected through the opposite nostril, might in some cases prove effective in dislodging the concretion. According to Frankel, sternutatories were worthy of trial. The dental engine might render signal service. In the post-nasal extraction of a calculus, strict precautions must be adopted to prevent it from falling into the larynx.

The remainder of the paper contained many useful hints, both for the patient and for the surgeon, in regard to the precautions to be taken, but often neglected, in treating nasal disease.

Dr. F. O. STROCKTON remarked that the writer of the paper had omitted to mention one very simple method of removing these calculi, which consisted in making strong pressure through the posterior portion of the throat and nares, and thus expelling it through the anterior nares, which was certainly much to be preferred to removing the calculus through the posterior nares. Another method was by using a small loop of iron wire, rotating the wire upon the stone, and thus extracting it anteriorly. He then cited a case which had come under his observation, and described the method he had pursued in removing the calculus. It was irregular in shape, and had produced absorption of some of the small facial bones by puncturing or passing through them. A dental engine with a diamond drill was used to break the stone, and it was removed in this manner piecemeal. He knew of no other case ever having been treated and the stone removed in this manner. The method of boring was by drilling in different directions with a dental drill, and, as there was no pressure made, the mucous membrane and other soft tissues were not injured. This case he had treated while in London, and the engine employed was the one used by Dr. Goodwillie, of New York. L. H. M.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twentieth Annual Session, held at the Grand Hotel, Catskill Mountains, N. Y., Wednesday and Thursday, July 16 and 17, 1884.

Wednesday's Proceedings.—Morning Session.

The meeting was called to order by the vice-president, Dr. W. F. NORRIS, of Philadelphia.

The Treasurer's Report was presented and referred to an auditing committee, which reported the accounts correct.

The Secretary and Treasurer, Dr. RICHARD H. DERBY, of New York, resigned his position, and Dr. O. F. WADSWORTH, of Boston, was elected to these offices.

Invited Guests.—By invitation, Dr. SUTPHEN, of Newark, N. J., Dr. PARROT, of Brooklyn, and Dr. ANDREWS, of Philadelphia, took seats with the society.

Iridectomy in Chronic Iritis.—In a paper with this title Dr. HASKET DERBY, of Boston, related the case of Miss D., aged sixty, who had suffered from many attacks of recurrent iritis. These were relieved readily by the use of atropine, but their occurrence could not be prevented except by the continuous use of atropine. She finally passed into other hands and glaucoma was diagnosed. Iridectomy was then performed on both eyes. The attacks of iritis gradually became less frequent after the operation. Dr. Derby did not consider this a proof of the

beneficial effect of iridectomy, but was disposed to attribute it to the gradual wearing out of the disease.

Dr. H. KNAPP, of New York, said that in many cases the attacks of iritis subsided spontaneously. He would not perform iridectomy in ordinary genuine iritis, but where there was, in addition to inflammation of the iris, a tendency to cyclitis and glaucoma, he considered the operation indicated.

Cases of Restoration of the Eyelid by Transplantation of a Flap without a Pedicle, by Wolfe's Method, was the title of a paper by Dr. CHARLES S. BULL, of New York, in whose absence it was read by the secretary. The histories of three cases of great eversion of the lids, the result of cicatrization following burns, were given. In two of them the upper and in one the lower lid was the part affected. The adhesions were loosened, the surface was freshened, and a flap, removed in two cases from the forearm and in the third from the anterior wall of the chest, was applied to the raw surface and confined in position with as many sutures of fine black silk as were necessary. Over this was placed a dressing of goldbeater's skin, iodoform gauze, and borated cotton, the whole being held in place with a bandage. The dressing was not disturbed for three or four days. In the case in which the lower lid was operated on there was sloughing of the epidermal layer of the flap, but in all the cases great improvement was effected.

A Successful Case of Skin Transplantation, without a Pedicle, to the Lower Lid after Removal of an Epithelioma, was the title of the next paper, by Dr. B. E. FRYER, of the army. The epithelioma had existed one year and was steadily extending. It was removed by excision, and, after the lids had been fastened together with two sutures, the gap was filled with a flap removed from the forearm and prepared in the usual way. No stitches were inserted in the flap, but it was held in position with gold-beater's plaster, which was applied moistened and pressed into all the inequalities. Two layers of plaster were applied. When they became dry, they formed a firm splint and kept the edges in perfect coaptation. The patient was exposed to cold after the operation, and, to protect the wound, a pad of cotton was applied, but this was removed on the patient's arrival at her home. On the eighth day after the operation the plaster was removed and union found to be perfect. Three months afterward there had been little contraction.

A Case of Gangrene of the Lids, with Subsequent Restoration of Tissue without Plastic Operation was reported by Dr. RICHARD H. DERRY, of New York. Two weeks before coming under observation the patient noticed a small black discoloration. This was followed the succeeding day by swelling of the face. When he was first seen, the upper lid was in a sloughy condition. The patient was lost sight of for a month. When he returned, it was found that the skin had reproduced itself and that there was little deformity, the patient having incomplete control of the lid.

Hysterical Unioocular Blindness with Mydriasis and Blepharospasm was the subject of a paper by Dr. GEORGE C. HARLAN, of Philadelphia. The patient was treated in different ways for some time. Finally a Charcot magnet was applied, to see what effect it would have on a severe spasm of the face which was present. It relieved the spasm and also produced improvement in the sight. The experiment was repeated several times, and always with the same result. It was then decided to try the effect of an imitation magnet made of wood. With this the results were even better than with the real magnet. An hysterical affection of the elbow joint, which followed a fall during the course of the treatment, was also successfully treated with the imitation magnet.

Neuro-retinitis with Fulminant Blindness.—Dr. KNAPP, in a paper with this title, related the case of a gentleman, with

no constitutional disorder, who suffered, on May 3, 1883, with severe headache and nausea. The following night he slept well, but the next morning, on awakening, found that he could not see. The only abnormality which could be discovered was suppression of urine. The catheter was introduced and only half an ounce of urine withdrawn. Ophthalmoscopic examination showed well-marked choked discs in both eyes. Examination of the urine showed the absence of albumin, sugar, and casts. The most probable explanation of the attack was uræmia, and in this a number of prominent physicians concurred. Diaphoresis was induced by the administration of salicylate of sodium and calomel. This treatment was continued, and gradually the quantity of urine increased. Two months after the occurrence of the blindness the patient said that he could see a little. His ability to see became more marked, and at last he was able to make out large letters and see the pictures on playing cards so as to distinguish one from another at a distance of two feet. The object had to be held in a certain position and at some distance from the eye. There had been no further improvement in vision. It was thought that the probable explanation of this case was the occurrence of some cerebro-spinal lesion or of some difficulty about the chiasm in the frontal lobes of the brain.

Another case was related, which was that of a little girl aged twelve years. For two days there were short attacks of dimness of vision. She then, on awakening one morning, found that she was unable to see with the left eye, and by noon the right eye was also blind. Examination of the eyes showed both pupils to be immovable. Both discs were swollen, the arteries small, the veins large but easily emptied by pressure, which caused the arteries to pulsate. Diaphoresis and diarrhœa were induced by the use of salicylate of sodium and calomel. In two days there was slight perception of light, and from this time improvement was rapid. In two months the vision was normal.

Dr. Knapp thought that there might have been some cause of pressure about the optic chiasm or the cavernous sinus which was removed by the free discharge from the bowels.

Dr. CHARLES J. KIPP, of Newark, N. J., said that he had always been taught to attribute optic neuritis to a cerebral lesion, but some cases which he had seen had led him to the opinion that the condition might sometimes be referred to other causes.

Dr. KNAPP called attention to the fact that there might be serious disease of the frontal lobes of the brain continuing for a long time without producing any alarming symptoms.

Dr. HARLAN stated that he had examined a large number of inmates of asylums for the blind, many of whom had atrophy of the optic nerves and yet were in excellent health.

Dr. A. ALT, of St. Louis, had seen a case of optic neuritis in which there were very serious general symptoms, the patient's life being despaired of. The trouble was attributed to a brain tumor. Large doses of iodide of potassium were administered and the child entirely recovered her health. Atrophy of both optic nerves remained.

Hereditary Atrophy of the Optic Nerve.—In a paper with this title the VICE-PRESIDENT gave the history of a family of twenty-three persons, of whom fourteen suffered from this affection. He also exhibited a number of charts showing the results of testing their appreciation of color, and the extent of the visual field in the different cases. The treatment, which consisted in the use of corrosive sublimate and strychnine, had proved of no service, only one case showing any improvement under the use of these drugs.

Two Cases of Orbital Tumor was the title of another paper by the VICE-PRESIDENT. The first was one of myxo-

sarcoma occurring in a child four months old. The growth was removed, but returned. It was again operated on and the actual cautery was applied, but it again appeared. At the present time the child was said to be very ill, suffering with a bloody diarrhoea.

The second tumor was an osteoma of the orbit. It developed in a woman thirty-two years of age. The sight of the eye had been lost before the development of the tumor. In operating on the growth, it was found that it extended so far back that the eyeball would have to be removed. This was done and the tumor was chiseled away. The woman recovered, and there had been no return of the disease.

Jequirity was the title of a paper by Dr. J. A. ANDREWS, of New York. He thought that the ordinary method of using the drug was not a good one. He then described his plan, which was to prepare a cold one-per-cent. infusion of the bean. This was brushed over the conjunctiva. The patient was to be examined again on the following day, and the application repeated as often as required.

The VICE-PRESIDENT, in a case in which he had employed the infusion of jequirity, had found that after a time the membrane lost its susceptibility to the action of the remedy.

Dr. H. S. SCHELL, of Philadelphia, did not consider it so important to use a fresh preparation. He had employed with success an infusion which had been made several weeks. Its activity had been preserved by the addition of four grains of boric acid to the ounce.

Dr. WADSWORTH had used an infusion to which two per cent. of carbolic acid had been added. This preserved its virtues.

Dr. J. S. PROUT, of Brooklyn, had called the attention of the society some years ago to the use of quinine in the affections for which jequirity had been recommended. He had reported two cases in which good results had followed the use of this remedy. Its use was not attended with the same dangers as that of jequirity.

An afternoon session was held at four o'clock to enable the society to examine a number of microscopical specimens prepared by Dr. ALT. At the same time Dr. E. DYE exhibited and explained a new form of perimeter.

(To be concluded.)

AMERICAN OTOLOGICAL SOCIETY.

Seventeenth Annual Meeting, held at the Grand Hotel, Catskill Mountains, N. Y., Tuesday, July 15, 1884.

Morning Session.

THE meeting was called to order by the vice-president, Dr. J. S. PROUT, of Brooklyn.

The Business Committee.—The following-named gentlemen were appointed to serve on the committee: Dr. F. B. LORING, Dr. E. W. BARTLETT, and Dr. A. ALT.

The Treasurer's Report was read and referred to an auditing committee. Dr. THOMAS ANDREWS, of Philadelphia, was then introduced to the society as a guest.

On the Indications for opening the Mastoid Process, based on some Recent Observations.—Dr. H. KNAPP, of New York, read a paper with this title, in which, after referring to his former disinclination to operate when there were no external signs of suppuration, and when, in acute otitis media, there was free discharge through the external meatus, he stated that he had changed his opinion on these two points, and now considered the operation indicated in certain cases in which the membrana tympani was intact and no suppuration or collection

of fluid was to be looked for in the tympanic cavity or the mastoid cells. He then related three cases illustrating the value of this operation in different conditions. The first case was one of acute tympano-mastoiditis, in which rapid recovery followed after opening of the mastoid cells and the liberation of a great quantity of pus. The second case was one of chronic suppurative tympano-mastoiditis, with chronic unilateral headache, in which relief followed the operation. In the third case there was sclerosing mastoiditis, with the membrana tympani intact, and with constant severe headache. In this case opening of the mastoid cells gave complete relief. The reader then described his mode of operating, which consisted in making an incision one cm. from the insertion of the auricle, making the perforation, when there was no special reason for choosing some other point, at the depression behind the upper level of the meatus. For opening the cells he used only the chisel, and made the opening oblong with its greatest diameter vertical. The canal thus made ran in the direction of the canal of the ear. If it was desired to have the wound heal by first intention, it was united with a continuous suture of fine black silk. If suppuration set in in a few days after the operation, the wound was syringed with a solution of chloride of sodium or of boric acid. When suppuration and putrefaction were present, before or after the operation, iodoform powder was employed.

Mastoiditis Interna Chronica with Sclerosis; Trephining; Recovery.—Dr. J. A. LIPPINCOTT, of Pittsburgh, Pa., read a paper in which, after remarking that the literature of this affection was so meager that the report of another case might not be without interest, he related the following case:

Miss N., aged nineteen, presented herself March 15, 1883, complaining of moderately severe pain which had lasted several months. There was no history of nasal or throat trouble. Her previous health had been good and her family history was excellent. A watch was heard on contact with the auricle. On removing a quantity of wax found in the canal, the latter, together with the membrana tympani, was found unusually red and irritated, and the hearing was but slightly improved, $h = \frac{1}{16}$. The left ear was normal. The naso-pharynx was slightly catarrhal. The middle ear was easily inflated. A solution of boric acid and sodium biborate was directed to be instilled several times daily, and the patient was requested to return if the pain did not subside entirely.

Five weeks later the pain, which had been but partially relieved by the removal of the cerumen, and the subsequent application, became greatly intensified, being referred partly to the region of the middle ear and partly to the mastoid process, occasionally shooting over the whole side of the head. There was considerable swelling and tenderness over the process and below it. The external canal was diminished in caliber. There was no congestion of the membrana tympani. The typical light cone was absent, but the anterior two thirds of the membrane showed a silvery luster. The Eustachian tube was pervious. There was slight febrile disturbance. Free leeching, poultices, and, internally, the mild chloride and a febrifuge mixture caused the acute manifestations to subside quickly.

April 28th.—Her condition was as follows: Constant dull pain in the mastoid and deep in the ear. No swelling. Membrana tympani as before. Hearing $\frac{1}{16}$. A tuning-fork applied to the vertex was heard best on the affected side. During the succeeding months the pain gradually increased in intensity, and became more localized in the mastoid region—never over the side of the head. Hearing slowly failed till the watch was heard only on firm pressure. No cerebral symptoms and no swelling occurred at any time. The treatment consisted of blisters, tincture of iodine, various ointments, incision, etc. Internally, alterative, roborant, and anti-neuralgic remedies were

given in various forms. As time wore, on the long-continued suffering began to produce nervous debility and mental depression.

March 20, 1884.—The patient was etherized, and an incision an inch and a half long was made half an inch behind the auricle. The periosteum was firmly adherent. Buck's drill was applied at the usual point and an opening was made 17 mm. in depth. The osseous tissue was dense and ivory-like. No mastoid cells were encountered. A carbolyzed tent was inserted and a poultice applied. The pain was at once greatly diminished, and in a few weeks disappeared entirely. The opening closed May 16th. Three weeks later, owing to exposure and fatigue, there was a slight return of the pain, which, however, promptly subsided on the application of an ointment of belladonna and the yellow oxide of mercury.

July 8th.—The patient was perfectly free from distress, and the hearing had improved to $\frac{3}{5}$.

Dr. ALBERT H. BUCK, of New York, considered it unwise to try to secure union by first intention after operation on the mastoid process, as had been suggested by Dr. Knapp. The operation did good by favoring drainage and exciting irritation.

Dr. KNAPP stated that the only case in which he had attempted to secure union by first intention was one in which the lateral sinus had been opened.

Dr. C. J. KIPP, of Newark, N. J., reported a case in which, while there were no external evidences of disease, an exploratory incision down to the periosteum revealed caries of the bone one inch back of the attachment of the auricle. As soon as the operation was performed, relief from the symptoms was obtained.

Dr. SAMUEL THEOBALD, of Baltimore, had employed constitutional treatment in these cases with decided benefit, such treatment often curing the disease without operation. Among the remedies particularly recommended were biniodide of mercury and iodide of potassium.

Dr. SAMUEL SEXTON, of New York, stated that in many of these cases spontaneous cures occurred, and he exhibited photographs illustrating such cases. Pain alone did not constitute sufficient evidence of involvement of the mastoid cells. In some of the cases in which eburnation was said to have occurred, the condition met with might have been due to the fact that the perforation had been made near the canal, where the bone was naturally denser than in other situations.

Dr. W. W. SEELY, of Cincinnati, described a case of severe pain in the mastoid region, with suppurative of rather long standing, associated with facial paralysis. It was thought that an operation was indicated, but before its performance a twenty-grain dose of quinine was given, after which the pain disappeared and had never returned.

Dr. J. A. ANDREWS, of New York, considered the presence of optic neuritis or swelling of the optic disc an important indication for the operation, and cited cases in which, guided by this condition, in the absence of other indications, he had performed it with decided benefit.

Dr. ARTHUR MATHEWSON, of Brooklyn, did not consider the operation advisable in sclerosis.

Dr. B. E. FRYER referred to the importance of operating before the patient became so debilitated as to make the occurrence of pyæmia after an operation very probable.

Dr. J. A. LIPPINCOTT spoke of the use of alteratives and anti-neuralgic remedies in the treatment of these cases.

Dr. BRUCE said that, in considering such cases, the first question he decided was whether the mastoid disease had developed as an acute trouble in a person previously in good health, or whether it had developed in one who had been suffering from a chronic discharge from the ear. Having settled this point, the

next was whether or not there was a sufficiently free exit for the discharge. In chronic cases there might be serious disease of the mastoid cells without marked external symptoms. If in a chronic case the opening for the discharge of matter was not adequate, the mastoid process should be opened. In the acute cases there was more room for discussion, but it was considered good surgery to operate on the mastoid. He thought that drainage could be accomplished more satisfactorily through such an opening than through the meatus.

Dr. SEXTON advocated drainage through an opening made from the external meatus.

Remarks on the Use of Large Doses of Iodide of Sodium or Iodide of Potassium in Cases of Rapid Loss of Hearing supposed to be due to Syphilitic Disease.—Dr. BRUCE read a paper with this title. After referring to several cases which had been reported by others, in which benefit had followed anti-syphilitic treatment, he described a number of cases treated by himself with large doses of iodide of potassium and of sodium, in the majority of which no improvement had occurred, while in one or two there had been slight temporary benefit. The doses of the iodide ranged as high as 525 grains a day in one case.

A number of other cases were reported by the members in which this treatment had failed to produce benefit.

Dr. SEXTON thought that in the severe cases relief was not obtained by any plan of treatment, and that in those cases amenable to treatment benefit would be produced by moderate doses of anti-syphilitic remedies continued for a moderate time.

Dr. BRUCE had reached a similar conclusion. The probable reason why these cases were so little affected by treatment was that the syphilitic gumma, or whatever it might be, which caused the trouble had so pressed on the labyrinth as to destroy the part with which it came in contact, so that, although the gumma might be absorbed, the part was so injured that it did not regain its function.

Evening Session.

The Education of Deaf-Mutes was the subject of a communication from Professor F. E. CLARKE, which was presented by the secretary. Dr. Clarke was invited to present his paper to the society.

The Treatment of Suppurative Otitis Media with Jequirity.—Dr. W. W. SEELY, of Cincinnati, read a paper in which he said that we had had time now to recognize the shortcomings of the latest contribution to our treatment of chronic suppurative inflammation of the middle ear, and boric acid had its shortcomings along with the entire catalogue of remedies and plans. Each year established on a firmer and broader basis the necessity of fulfilling certain conditions in order to obtain the greatest success in this class of cases: first, *cleanliness*; second, *rendering and maintaining the Eustachian tubes patulous*; and third, *getting the naso-pharynx into a healthy state*. He was satisfied that this last point was too little regarded by some and utterly ignored by many. He called attention to the fact that the mucous membrane of the tympanic cavity got into such a state that practically it could only be relieved by changing it into cicatricial tissue—a condition analogous to the state of things we found in trachomatous inflammation of the conjunctiva. This condition of the conjunctiva had recently been combated by means of exciting an inflammation of considerable violence with infusion of jequirity. For a year or more he had been treating certain long-standing cases of suppurative otitis media by exciting an additional substitutive inflammation with jequirity, using a small quantity of the preparation made for the eye. He was inclined to think that such inoculation was capable of playing an important rôle under certain conditions:

When there was extensive destruction of the membrana tympani; when there was a great amount of thickening of the mucous membrane, thus rendering other plans futile or tedious; and when there was a patulous Eustachian tube—a condition for regulating the inflammation.

Disease of the Ethmoid, the Consequence of Chronic Catarrh of the Naso-Pharynx; Exophthalmus.—Dr. J. J. B. VERMYNE, of New Bedford, Mass., read a paper in which he related the case of a healthy-looking young lady of sixteen, who had a slight protrusion of the right eye, which had been observed for some time. The eye was pushed forward and outward. There was neither swelling of the lids, dilated veins, nor conjunctival redness or pain. The optic disc was slightly raised, and the retinal vessels were distended. Vision in both eyes = 1; slight H. on the right side. For a few days she had been complaining of headache. She had in general enjoyed good health, with the exception of chronic naso-pharyngeal catarrh, especially on the right side, which had troubled her since her fifteenth year, when she had a severe attack of scarlet fever. There was no interference with the movements of the eyeball or with binocular vision, with the exception of slight diplopia on awaking in the morning, which passed off quite rapidly. A neoplasm was suspected in or around the nerve, and no treatment was advised in consequence. The headache passed away and, with the exception of the slight deformity from the protrusion, she felt entirely well. It occurred to the writer that after all the disease might not be a neoplasm in or around the nerve, and, after making another careful examination, found that there was a tumor of bony hardness, slightly nodulated and immovable, stretching from the upper inner corner of the eye to a little below the ligamentum canthi internum, and distinctly connected with or originating from the os planum. The disease was then referred to the naso-pharyngeal catarrh, and treatment was advised accordingly. The writer believed this case to be one of retention tumor, a case of which was reported by Dr. Knapp at the International Ophthalmological Congress in 1876. This belief was based especially on the fact that the patient's mother told the author afterward that frequently she had observed a peculiar appearance of the eye which she compared to a "lobster eye," but which disappeared after some days. Dr. Knapp's patient was successfully operated on with a chisel and hammer—an operation which was by him advised in all cases of this kind, whether of exostosis or of retention tumor. Another case of Dr. Knapp's was quoted from the "Archives of Otolary" for April, 1884, where the operation was performed and the patient died from traumatic meningitis. The predisposing cause of this condition was found in a disease of the osseous walls of the frontal sinus, the exciting cause being the surgical interference. The writer, reviewing the conclusions drawn by Dr. Knapp from this last case, believed that it became pertinent to ask what constituted a perfectly healthy pneumatic cavity, and whether some participation of the bone in the neighborhood of the tumor could not with more or less reason be suspected. Also, in view of the lesser danger which might attend simple mechanical distension of the bone, whether an exploratory puncture with a trocar, as advised by other writers, might not become imperative in place of being unnecessary, as Dr. Knapp had stated in the report of his first case, and whether in tumors of this kind, when not endangering the eye and not of inconvenient size, it would not be better to leave them alone, as advised by other authorities.

Dr. KNAPP stated that many of these cases were due to nasal polypi.

Dr. KIPP, of Newark, N. J., reported the case of a patient who had died of pneumonia eleven days after operation, in which the frontal sinus, the ethmoid cells, and the sphenoidal

sinus were filled with polypi. In another case he had succeeded in relieving the difficulty by pressure with the finger.

Myxofibroma from the Basis Cranii causing Blindness and, Seven Years later, Complete Deafness by Destruction of the Labyrinth.—Dr. VERMYNE read an account of a case which was first seen in January, 1876, when there was a complaint of occasional dimness of vision and fatigue of the eye. Vision $\frac{1}{16}$. There was no other complaint. The optic disc and the retinal vessels were slightly congested. At the end of April of the same year severe headache and optic neuritis developed. Under the administration of large doses of bromide and iodide of potassium and the use of Heurteloup's artificial leech, improvement set in, but the writer then lost sight of the patient. She was seen again five years later, when both discs showed secondary atrophy. Two years afterward she became deaf, but at the end of six weeks she began to hear as well as before; then hearing gradually disappeared, and in May, 1884, the patient died, nearly eight years and a half after the first observation by the writer. At the autopsy a tumor was found, 6 cm. long, 4 cm. wide, and 2 cm. thick, in the left inferior occipital fossa, which had compressed the left cerebellum to one third its normal size. Both the brain and the cerebellum were anæmic, and the latter of increased consistence. There was much fluid in the ventricles. The most recent part of the growth had impinged upon the petrous portion of the left temporal bone, causing the entire destruction of the bone between the posterior wall and the tympanic cavity, which was opened. The tumor was a myxofibroma. The writer believed the first indications of the tumor to have been the eye symptoms, occurring before any other complaint; that probably the tumor originated from the dura mater, and that its effect upon the organs of sight and hearing was due absolutely to interference with the circulation from mechanical pressure.

Epithelioma of the Auricle.—Dr. KIPP described a case of this sort. It occurred in a healthy boy of nineteen. It appeared one year before the case came under observation. The concha was the seat of a small fleshy growth, with a granular surface. On the upper part of the auricle there were several boils, and below the ear was an enlarged gland. The hearing was not impaired. The diagnosis of granuloma was made, and its removal was advised. This was done, the whole growth being thoroughly removed with a sharp spoon. The wound healed completely in about a week. At this time a furuncle developed in the external canal, and others appeared under the ear. Since then the patient had not been seen. Microscopical examination of the growth showed it to be made up largely of epithelial cylinders. The stroma was very vascular.

Dr. Kipp demonstrated also a specimen of a cavernous fibrolipoma which he had removed from the upper part of the auricle of a man thirty-five years of age. The growth had existed for several years, but had not grown much until a month before he saw the patient. The tumor, which was of about the size of a hickory-nut, was removed by excision. There was but little hæmorrhage, and the wound healed kindly. Microscopically, the tumor was found to be a lipoma, with considerable fibrous tissue between the lobules, and these had undergone cavernous metamorphosis. Growths of this kind were believed to be rarely found in this locality. Dr. Kipp showed also a very large atheromatous tumor which he had removed from the helix.

Hæmatoma Auris.—Dr. L. Howe, of Buffalo, described a case, in a woman of twenty-eight years of age, which had been relieved by the hypodermic injection of ergot, and he presented plaster casts showing the condition of the ear at different stages of the treatment. He thought, however, that the same result might have followed the injection of other agents.

Dr. SEXTON presented a number of photographs illustrating

othæmatoma. He referred to the frequent occurrence of this condition among pugilists, in whom it was produced by blows on the ear. In them it was almost invariably on the left side. He thought that othæmatomata in the sane were always the result of injury, and that in the majority of instances in the insane it was due to the same cause.

Dr. HOWE thought that some other cause than injury must be looked for in these cases.

Dr. SEXTON presented the report of a case of sarcoma of the auricle, also a number of photographs illustrating various malformations of the auricle. He then exhibited several plaster casts of the mouths of patients who were suffering from aural troubles which were referable to dental irritation. He likewise referred to the use of peroxide of hydrogen in the treatment of aural inflammations. He had used it with advantage.

Necrosis of the Right Labyrinth; Total Facial Paralysis on the Same Side; Partial Recovery.—A paper on this subject, by Dr. CHARLES A. TODD, of St. Louis, was read by title. We are permitted to publish the following abstract of the paper: The patient was a girl, nineteen years old, who, when four years of age, had had measles, followed by a discharge from both ears, which had persisted up to the time of her attendance at the clinic, four years later. Under treatment, the left ear ceased to discharge, and the perforation healed. As was common with out-patients, she attended only when the disease was annoying, so that the right ear, although at times nearly well, was not allowed to become entirely relieved of the suppuration. In November, 1882, Dr. Todd was asked to visit her, and found her suffering from severe deep-seated pain in the mastoid region, but without any external redness or swelling. This pain had been increasing gradually for thirty days. After three days of treatment with hot applications and anodynes (operation on the mastoid not seeming justifiable), the pain ceased, and total paralysis of the right side of the face became manifest. A year afterward, when she was seen at the clinic, granulations were protruding through a perforation in the upper posterior quadrant of the right membrana tympani, but no dead bone could be detected. The patient disappeared after these granulations had been got rid of. In March, 1883, a part of the cochlea was removed in a state of necrosis, and soon after, under the dry method of treatment, the ear ceased to discharge. The paralysis was complete, and, in view of its cause, of course the prognosis was not hopeful. The continuous galvanic current was applied irregularly and cautiously—more to satisfy the patient than for any other reason, and after that, under the use of the faradaic current, the distorted mouth and the partially closed eyelids were brought into more tolerable condition, as some will-power developed. Since the beginning of spring the battery-current had been used three times a week, with evident improvement of the innervation of some of the facial muscles, while others remained irresponsive. The corner of the mouth could be drawn well back and raised somewhat, and it could be fairly puckered as if to whistle. The lids could be closed, but not with the natural degree of force. Evidently the facial nerve was partially restored in some of its fibers.

Reflex Aural Phenomena from Naso-pharyngeal Catarrh; Objective Noises in and from the Ear.—A paper with this title, by Dr. C. H. BURNETT, of Philadelphia, was read by title. We are allowed to give the following abstract:

The author described three cases of objective snapping noises in and from the ears, which could be heard at varying distances from the patient. These noises occurred in subjects of naso-pharyngeal catarrh, and it was held by the speaker that they were due to clonic spasms in the muscular structures of the naso-pharynx, induced by the irritation reflected from the inflamed mucous membrane covering or in the vicinity of the mus-

cles involved. The muscles affected in the cases reported were the levator palati, the superior constrictor of the pharynx, near the Eustachian tube, and the pterygoid muscles. When the latter muscles were the seat of spasm the noises were heard in both ears, and the lower jaw was moved from side to side each time the noise occurred. In two of the cases the sounds could be heard ten or twelve feet from the patient. In these cases the muscles involved were the levator palati and the pterygoid muscles. In the case in which the superior constrictor muscle was the seat of the spasm the sound could only be heard by means of the auscultation-tube. It was, however, distinctly audible to the patient. The production of these objective sounds was explained by the irritation of the sensitive nerves in the inflamed area, the conveyance of the irritation to the motor nerves of the tract, and the resultant endeavor of the muscles underlying the inflamed mucous membrane to throw off the irritant. That this was the correct explanation was shown by the fact that in two cases the noises disappeared when the catarrhal symptoms were relieved. The case in which the pterygoid muscles were implicated is still under treatment. So far as Dr. Burnett was aware, he was the first to suggest the cure of objective noises in and from the ear by treating the naso-pharyngeal catarrh which was the reflex cause of their occurrence.

A paper entitled "**A Simple Device for the Treatment of Nasal and Post-nasal Inflammations, and on the Importance which attaches to such Conditions of Inflammation as they are related to the Ear,**" by Dr. H. N. SPENCER, was read by title and referred to the Committee on Publication.

The Education of Deaf-Mutes.—Professor CLARKE's communication, asking for certain information which might be of service, in the education of deaf-mutes, was referred to a committee of three, the president of the society to be the chairman of the committee.

New Instruments were shown by Dr. THEOBALD, Dr. SEXTON, and Dr. ANDREWS.

New Members.—In executive session the following new members were elected: Dr. E. D. SPEAR, JR., of Boston, Dr. JOHN VAN DYKE, of Syracuse, N. Y., and Dr. S. O. RICHEY, of Washington.

Officers for the Ensuing Year were then elected as follows: President, Dr. C. H. BURNETT, of Philadelphia; vice-president, Dr. J. S. PROUT, of Brooklyn; secretary and treasurer, Dr. J. J. B. VERMYNE, of New Bedford, Mass.; Committee on Publication, Dr. VERMYNE, Dr. C. J. BLAKE, and Dr. J. O. GREEN; Committee on Membership, Dr. JOHN GREEN, Dr. H. G. MILLER, and Dr. H. D. NOYES.

It was voted to hold the next meeting at the same place with the annual meeting of the American Ophthalmological Society, and on the day before the meeting of that society.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Meeting of June 4, 1884.

On a Form of Numbness chiefly of the Upper Extremities.—Dr. WHARTON SINKLER read a paper with this title. For several years he had observed in his service at the Infirmary for Nervous Diseases, and occasionally in private practice, quite a large number of patients whose prominent symptom was numbness of the hands. The symptoms were quite regular and constant in their general characters. The patients were usually women—at about the change of life—although cases occurred in men. The numbness generally began in one or both hands and gradually extended up the arms. It might be felt in the feet and legs also. It was almost always most marked in the

morning before the patient rose. It was described as a "tingling," and "like pins and needles," or as if the limb "were asleep." One patient, in whom the numbness was felt in both upper and lower extremities, said she felt like "a sleeping fool." Notwithstanding the numbness, there was but little loss of feeling to touch or pain, and usually the compass points were distinguished as readily in the affected part as in other portions of the body. The numb member was weak, but there was no paralysis, and the weakness was transient. Often there was pain associated with the numbness. The patients sometimes thought the hands were swollen at the time when the numbness was most marked.

It must be borne in mind that he did not consider all cases of numbness as coming under this head. There were many which did not depend upon organic lesions of the nervous centers and yet differed from those which he was considering.

Brief notes were then given of nine cases. Of the female patients whose cases were given, their ages were between forty-eight and sixty years, with the exception of one who was thirty years. In this case the disorder was induced by the nature of her work, which was constant and hard sewing. The ages ranged as follows: one aged thirty years; one, forty-eight; three, fifty; one, fifty-one; one, sixty. In two patients there were evidences of rheumatism, but in none of the others were there any symptoms of rheumatic trouble. In three the origin of the trouble seemed to be in overuse of the limb first affected. Indeed, in one case the affection at first seemed like a low form of ascending neuritis, but afterward the symptoms were more general. Most of the patients were in good general health, but some were anæmic or overworked.

The numbness in most instances was in both arms, occasionally it was found in all of the limbs, and in three cases in one arm alone. The ulnar and median distributions were most frequently affected. Pain was associated with the numbness in several patients. It was not an acute pain like neuralgia, but, as one patient expressed it, like the pain when a limb was getting over being asleep. Tenderness over the ulnar or median nerve was observed several times. There was usually some loss of power in the parts involved, the dynamometer showing several degrees difference between the hands when only one limb was affected. The duration of the affection was from a few months to several years. One of the patients had suffered from the disorder for two years before coming under observation, and at the end of a year and a half still had occasional attacks.

Dr. Weir Mitchell, in a lecture on "The Symptom Numbness,"* and afterward in a chapter in his work on "Diseases of the Nervous System," had described several varieties of numbness. Most of his cases were in anæmic or hysterical persons, and the symptom yielded under a course of treatment which tended to improve the nutrition and the *morale*. He referred to cases in which the numbness came on during sleep, and remarked that this was a form which belonged to the night. He found that the numbness in the cases he had seen was frequently hemiplegic in character, and alluded to the fact that some persons who had got pretty well of a hemiplegia of organic cause were liable to wake out of sleep with numbness and lessened power of the side once palsied.

Dr. James J. Putnam, in a paper read before the American Neurological Association,† treated at length of a series of cases of "paræsthesia mainly of the hands." He based his paper upon the notes of thirty-one cases, and the description he gave resembles those which had now been related. He found that most of his patients were women, and almost all were in middle

life, but he did not remark upon the fact that they were about the period of the menopause. Dr. Putnam suggested that the possible cause of the affection was "alterations of the blood-supply of the smaller branches or terminal filaments of the sensitive nerves supplying the affected districts."

The treatment by this writer consisted in the use of galvanism, phosphorus, strychnine, bromide of potassium, and several other drugs. He did not think that he had had sufficient opportunity to test the value of the different remedies, but seemed to have found phosphorus of more value than any other one means used.*

Dr. J. A. Ormerod had described twelve cases† which very closely corresponded to those which had come under Dr. Sinkler's observation. All of his patients were women, and the attacks of numbness began to come on about the cessation of the menses. Three of the patients were rheumatic, and in some the trouble proceeded from the nature of their work. Bromide of potassium afforded marked relief in many of the cases. Dr. Ormerod compared this affection to the deadness of the fingers which some persons experienced after exposure to cold, and therefore ascribed it to vascular spasm.

It had seemed to him (Dr. Sinkler) that in these cases there was probably a condition of hyperæmia either of the nerve-trunk or of a portion of the cord. In some cases he thought the hyperæmia was confined to the nerve-trunks or to some of the terminal filaments of the sensory nerves, but in others it seemed not unlikely that the cervical enlargement of the cord became hyperæmic or congested, from the fact that the numbness was often bilateral. The circumstance that the affection came on at night seemed to strengthen the view of the pathological condition being one of hyperæmia, for the supine posture favored an increase of blood in the cord and the nerves of the extremities. He had seen patients in whom the numbness would come on if they lay down and fell asleep even for a short time in the day. Women at the change of life were more prone to hyperæmias and congestions than at other periods of life, and they were the most frequent subjects of this form of numbness.

In several of his cases ergot gave marked relief, and Dr. Ormerod had found bromide of potassium the most successful therapeutic means he had used. Both these remedies were believed to diminish the blood supply in the nervous centers. It was true that Dr. Putnam had found phosphorus the most useful drug in his cases, but in one of those which he reported the remedy had failed, and in another relief was given with bromide of potassium. From his experience in these cases Dr. Sinkler would say that the prognosis in middle aged women was not good as regarded permanent relief. The numbness could generally be benefited greatly or stopped for the time, but it was liable to return. When the trouble had been induced by overwork of the part, one could almost surely promise permanent cure if the cause could be removed.

With regard to treatment, as already indicated, ergot had proved the most useful medicinal means he had employed. Massage and spinal galvanism were always useful adjuncts, and so were all means which improved the general health. Bromide of potassium had helped some of his patients, and one was much benefited by sinapisms over the spine. It was found advantageous in most cases to give strychnine for a time after the disappearance of the numbness.

* In a note recently received by Dr. Sinkler from Dr. Putnam, the latter says that he has lately found lead in the urine of one of the patients referred to in his paper, and thinks that it should be looked for in all cases of numbness.

A Study of the Nutritive Value of Branny Foods.—The following paper, prepared by Dr. N. A. RANDOLPH and Dr. A. E. ROUSSEL, was read:

From an economic standpoint the question of the nutritive value of bran is one of great importance, for the removal of this portion of the wheat implies a loss of from 17 to 20 per cent. in the weight of the grain. In spite of this loss, which necessarily renders white bread more expensive than that made from whole wheat-flour, even the poorest inhabitants of most civilized countries where bread is not the staple food insist upon eating the bread made from the finest flour. A tendency so wide-spread as this would apparently indicate the unconscious summation of the experiences of many generations, and go far toward proving the propriety of such a selection.

The use of flour representing the entire wheat-grain has, however, been long and ably advocated, the reasons given for the retention of bran being that its removal entails the loss of—

I. "Nutritive salts" (*Nährsalze* of Liebig).

II. Carbohydrates.

III. Proteids, notably gluten.

The facts also that branny foods, in common with many others, will spur an atonic bowel to activity, give due bulk to its contents, and induce the passage of stools of the normal or feculent consistence, are noteworthy, but their further consideration is beyond the limits of the present paper. The other reasons for the retention of bran in wheat-flour will be discussed *seriatim*.

I. The fact that fine flour contains a much smaller percentage of salts than either bran or the whole wheat does—a fact shown by the relatively small amount of ash which it yields—forms the basis of the theory of Liebig,* that in the removal of bran nutritive salts of value are lost. The investigations of Meyer† and Forster‡ are often cited as showing that, after the removal of bran, these salts are still present in quantity sufficient for the needs of the economy.

Our experiments upon young pigs, described farther on, show that, although survival is quite possible upon an exclusive diet of bread from white flour, growth is much more active upon a diet of bread containing a greater amount of inorganic matter. It is possible that Liebig's estimate of the needful amount of inorganic matters was too high, but it is equally noteworthy that there is a tendency on the part of late writers to give insufficient prominence to the importance of these elements of food. It may not be out of place here to mention a striking illustration of the absolute necessity for inorganic salts in the fluids of the economy, as recorded by Dr. S. Ringer.* This observer found that while minnows were kept in ordinary tap-water they would live for weeks unfed. When, however, they were placed in distilled water they died on an average in four hours and a half. Further, that in a rude imitation of spring water, made by the addition to distilled water of potassium and calcium chlorides, and of sodium bicarbonate, the fish lived on an average about two weeks. Study of the factors in the experiments showed that death was due to a diminution of salts in the economy of the fish. That such diminution, even when very slight, could result fatally, was shown by an analysis of the distilled water after the death of the fish, traces only of inorganic matter being found.

II. The loss of carbohydrates involved in the removal of bran appears at first sight not inconsiderable, as it amounts to

about 20 per cent. of the carbohydrates present in the entire grain. The members of this group represented in bran are starch and cellulose. The former is present in extremely small amount, while the latter, as has been proved by the experiments of Donders,* Mulder,† and Poggiale,‡ is digestible in any noteworthy degree* by the herbivora only. The observer last named subjected a given weight of dry bran to the successive actual digestions of two dogs and one hen, and thereafter was able to recover over 65 per cent. of its non-nitrogenous constituents. The loss in cellulose was probably much less than that here indicated, for we have found that during the maceration of bran in the digestive tract certain portions become detached from the main flake, and are with the greatest difficulty recovered.

III. Wheat bran contains a considerable but varying proportion of nitrogenous compounds, averaging, however, about 14 per cent.‡ This fact has permitted the continued existence of two widely credited assumptions: (a) That this nitrogen exists in albuminoid combination, or, in other words, is in a nutritious form; and (b) that the proteid matter of wheat is contained almost exclusively in specific cortical cells of the grain—the so called "gluten-cells."

(a) Nearly all the existing estimates of the proportion of proteids in food stuffs are based upon the hypothesis that all of the contained nitrogen is present in some albuminoid combination. The percentage of nitrogen in a given food is therefore ascertained, multiplied usually by either 6.5 (Payen) or 6.33 (Ritthausen), and the result recorded as the percentage of proteid matter. It has lately been conclusively proved that nitrogen in non-albuminoid combination—i. e., in compounds not capable of affording nourishment to any higher organisms—is present in many food-stuffs, and especially in those of vegetable origin. As a case in point may be mentioned the analyses of Wigner,^Δ in which it is shown that, of the total nitrogenous matter of the entire wheat-grain, 87.9 per cent. is coagulable—i. e., distinctively proteid. Of the bran, only 42.4 per cent. of its nitrogenous compounds are coagulable, whereas, in the flour, 89.7 per cent. of these bodies come under the head of true proteids. Yet more marked instances of the inaccuracies attending the ordinary methods of estimating proteids have become evident in the course of researches by Schulze and Barbieri,[◊] who find that, of the entire nitrogen of the potato, but 56.2 per cent. enters into the composition of albuminoid matter, while in the fodder-beet only 20 per cent. of its contained nitrogen is thus combined, the remaining 80 per cent. aiding in the formation of amides, nitrates, and ammonia. It is evident from these facts that estimates of the nutritive value of branny and other foods, based upon the percentage of nitrogen present, must be received with caution.

(b) The term "gluten-cell" is, through a wide-spread misapprehension, applied to the cells constituting the fourth layer (Parkes) of the wheat-grain. These cellular elements exist

Δ Dempwolf, "Ann. d. Chem. u. Pharm.," vol. xli, p. 343. His figures, of interest here, are as follows: The amount of nitrogenous matter in the whole wheat was 14.35 per cent. The amount varied in the different grades of white flour from 11.01 to 15.56 per cent. The nitrogenous matter of the two grades of bran made from this wheat was, respectively, 13.93 and 14.06 per cent.

usually in a single stratum, as irregularly cuboidal bodies in each of which, surrounded by a dense and laminated cellulose wall, are seen the semi-opaque granular contents. Upon the addition of reagents, especially in the form of caustic alkaline solutions, there is almost constantly noticeable a differentiation of the contents strongly suggesting the presence of a nucleus. Under these conditions, also, a coalescence of many of the individual granules forming the contents occurs, with the formation of several highly refractive spheroidal bodies, an appearance which has led Payen (as quoted by Dr. Richardson) to use the name *oléifères* as a synonym for the cellular constituents of the fourth coat. The hypothesis that the cells of this layer are the chief gluten-bearers of the wheat-grain is usually attributed to Donders.* The return of bran to flour was at about the same period also advocated by Millon and Mége Mouriès.†

From this time on, with but few dissenting voices, the "gluten-cell" has been generally spoken of as the index of the nutritive nitrogenous matter‡ of the wheat-grain, while the central portion included within this layer, and constituting fully 80 per cent. of the grain, has been popularly regarded as being made up almost exclusively of cellulose and starch, and attempts have even been made to estimate the nutritive value of certain cereal food-stuffs by a microscopical determination of the proportion of "gluten-cells" present.‡

The manifest impropriety of such methods has of late been strongly emphasized by Professor Richardson, of this city, and Professor Leeds, of Hoboken. The credit of the first disproof of the exclusive limitation of gluten to the cells of the fourth layer is probably due to Schenk,|| who treated sections of wheat-grain with Millon's reagent, a pink coloration of the endosperm resulting. This coloration was most vivid at the periphery, indicating a gradual condensation of the proteid constituents of the grain as the cortex was approached. The same writer found "no coloration of the 'gluten-cells' as a result of this reagent," an observation which we can not confirm; for, apart from the readily demonstrable slight coloration of the contents of "gluten-cells" after the application of Millon's reagent, it is more than difficult to conceive a cell, however specialized, which shall exhibit no proteid matter as a portion of its contents. Schenk also noted, in artificial gastric diges-

tions of sections of wheat, that the starch granules which (to a greater extent) fill the cells of the central portion of the grain became detached, and from this fact deduced the just proposition that the starch granules lay imbedded in some albuminoid substance. In a study of the distribution of gluten within the wheat-grain,* the senior writer has described several methods for the ocular demonstration of gluten, in very considerable amount, in that portion of the grain included within the fourth layer, and entirely independent of the "gluten-cells." The methods were as follows:

If whole wheat-grains be macerated in water, to which a few drops of ether have been added to prevent germination, they will in a few days become thoroughly softened, and the contents of each grain may then be squeezed out as a white, tenacious mass. Examination of the remaining bran shows the "gluten-cells" undisturbed, closely adhering to the cortical protective layers. By now carefully washing the white extruded mass, the major part of the starch may be removed; and, upon the addition of a drop of iodine solution, microscopic examination shows numerous networks of fine yellow fibrils, still holding entangled in their meshes many starch granules, colored blue by the iodine. In carefully washed specimens, the sponge-like networks are seen to retain the outline of the central starch-filled cells, and evidently constitute the protoplasmic matrix in which the starch granules lay. Upon gently teasing such a specimen under a moderate amplification, the fibrils will be seen to become longer and thinner in a manner possible only to viscid and tenacious substances—a class represented in wheat by gluten alone.

An eminently satisfactory proof of the proteid nature of these central networks may be obtained by heating the specimen in the solution of acid nitrate of mercury (Millon's reagent), when the fibrils will assume the bright pink tint characteristic of albuminoids under this treatment. The results of the application of the xanthoproteic and biuret reactions are equally conclusive, but more care is required in the use of these proteid tests, and the resultant differentiation is not so clear. Reticula similar to those above described, but much broken, and, consequently, far smaller, may be seen, upon close examination, scattered throughout fine white flour without the use of any reagent.

In even the thinnest sections of the wheat-grain the gluten of the central portion is always masked by large numbers of starch granules. These may to a large extent be removed by immersing the section for a short time in liquor potassæ, with subsequent careful washing. The alkali effects the hydration and partial solution of the starch; but, if its application be too long continued, the gluten will also be dissolved. This treatment is well adapted to show the rather dense gluten networks usually found adherent to bran immediately below the fourth layer.

The most satisfactory method of studying the distribution of gluten in sections of wheat is that of artificial salivary digestion. If the section be gently boiled for a moment to hydrate the starch, then transferred when cool to filtered saliva, and maintained for from half an hour to an hour, at a temperature of about 98° F., all the starch will be dissolved, while the insoluble proteid and other constituents will remain *in situ* and entirely unaltered. The same result may be obtained from a somewhat more prolonged digestion of the unboiled section. A section of wheat-grain thus treated will exhibit throughout its entire central portion close-meshed gluten networks, which become slightly denser toward the cortex of the grain. The proteid character

* "Nederl. Lancet," iv, 739; vi, 227, 244; Third series, vol. i, 377.

† "Comptes rendus," vol. xlv, p. 47.

‡ By general consent, the albuminoids of the wheat-grain are grouped together as gluten, which is, however, further separable into gluten-fibrin, gluten-casein, gliadin, and mucedin, proteid bodies practically equal in nutritive value, but differing in certain physical properties, notably that of solubility. It must therefore be borne in mind that, in all methods of separating gluten from the other constituents of the grain, its (relatively small) soluble portion is removed with the starch, and that any estimate of the quantity of gluten based upon such methods will probably be below rather than above the actual amount. Ritthausen ("Die Eiweiss-Körper der Getreidearten," 1872) believes that a certain amount of true albumin should be included with the constituents of gluten just mentioned. An observation of Denis ("Mémoire sur le sang," 1859), confirmed by Hoppe-Seyler ("Med.-chem. Unters.," 1867), and Weyl ("Ber. d. deut. chem. Ges.," xiii, 10, 1880), demonstrates that a portion of the proteids of the cereals exists in the form of a globulin. Thus, the observer last named has shown that in wheat-flour treated with a 15-per-cent. solution of sodium chloride no formation of gluten occurs. We have found that bran, when macerated in 15-per-cent. salt solution, yields a considerable amount of proteid matter precipitable by nitric and picric acids. We incline to believe, however, that this is not a true albumin. (See Vines, "Journal of Physiology," vol. iii, p. 93.)

§ E. Cutter, M. D., "Gaillard's Med. Jour.," Jan., 1882.

|| "Anat.-physiol. Untersuch.," p. 32, Wien, 1872.

* Randolph, "Proc. of the Acad. of Nat. Sci. of Phila.," Dec. 11, 1883, p. 308.

of these reticula is here, as in the first method, susceptible of micro-chemical demonstration. Upon the application of Milon's reagent to such a section, a relatively very faint coloration, indicating the presence of albuminoids, is noticeable in the "gluten-cells," while the gradual condensation of the gluten of the endosperm as the fourth layer is approached is evident even to the unaided eye.

The fact that the gluten networks become denser toward the periphery of the endosperm, together with the presence of non-albuminoid nitrogenous compounds in the perisperm, explains the notable percentage of nitrogen found in bran as ordinarily roughly removed.

The small proportion of albuminoids present in the cells of the fourth layer, as evidenced by their feeble response to the proteid tests, together with the very considerable quantity of gluten which we have shown to exist in the central four fifths of the grain (i. e., the portion lying within the fourth layer), justifies us in the conclusion that by far the major portion of the nutritious nitrogenous matters exists in entire independence of the "gluten-cells."

The difficulties which attend the complete isolation of these cells, however, have as yet rendered impossible any accurate estimation of the proportion of their proteid contents. Admitting for the moment that the "gluten-cells" contain albuminoids in any noteworthy amount,* there are yet present conditions which seriously affect, if they do not entirely nullify, the nutritive efficiency of this portion of the grain.

The first of these conditions is the presence of the rough bran scales which, by increasing peristalsis, so hasten the passage of the entire intestinal contents that complete digestion and absorption are prevented. The second is that, owing to the dense cellulose walls of the "gluten-cells," their contents are practically unaffected by the digestive juices. The fact that the presence of branny scales in the digestive tract prevents the thorough digestion of the intestinal contents and induces the passage of feces containing a considerable excess of undigested nitrogenous matter is fully attested by the observations of Meyer and Rubner.† Edward Smith‡ has also closely studied the economic phase of this subject, and reports most unfavorably upon the use of branny foods, stating that the diminished absorption of nutritive matters entailed by their use more than counterbalances the (apparent) gain in cheapness. Of interest in this connection is the observation of Fr. Hofmann,§ who noted that the amount of feces passed upon a meat diet was remarkably increased by the addition of cellulose to the food taken.

The feeble response of the "gluten-cell" to reagents and digestive juices has been noted by several observers. Thus, Donders|| states that these bodies are digested by the herbivora, but not by dogs or man. Similar results are recorded by Poggiel,^ and for domestic fowls by Meissner and Flügel.¶ J. Leh-

* Apart from the statement of Schenk, above cited, the entire absence of gluten in the cells of the fourth layer has been latterly affirmed by Mége Mouriés, who is quoted by Payen ("Substances alimentaires") to the effect that these cells are "filled with nitrogenous substances of which gluten is not at all one." He finds the cells in question to contain, in addition to the salts of magnesium, lime, and potash, a peculiar diastatic ferment, cerealine, whose function is the transformation of the starch of the grain into dextrin and glucose for the nourishment of the germinating seed.

mann* records the feeding of pigs for thirty-two days on bran which contained scarcely any flour, with a nearly negative change in weight, although the bran contained 15.5 per cent. of nitrogenous matters.

The ability of herbivora to digest "gluten-cells" and similar bodies is probably due to the relatively powerful amylolytic ferments of their digestive fluids, for it has been demonstrated that pepsin is unable to traverse cellulose.† It has also been shown by one of us‡ that the cells of the fourth layer are to all appearance entirely unaffected by prolonged artificial digestions—salivary, gastric, and pancreatic—and further that their contents were but little changed, and their walls in no wise disintegrated by immersion for some days in strong acids and alkalis.

Lately, however, in the course of an admirable paper upon the nutritive relations of gluten, Rubner§ has stated that, although branny foods increase the amount of nitrogen in the feces, fully three fourths of the nitrogenous matter of bran is digested. In the bran used there was present 4 per cent. of nitrogen, "equaling 25 per cent. albuminoids," while in the bran obtained from the feces of the persons under observation only 0.9 per cent. of nitrogen was obtainable. We hesitate in criticising the results of so able an observer, but it seems to us that there were two sources of error in this portion of his investigation. In the digestion of bran, the free, adherent gluten, which properly belongs to the more central layers, is of course readily dissolved with a consequent reduction in the nitrogen of the bran. Apart from this, however, a loss in nitrogen is to be expected from the diffusion of nitrogenous crystalloids; further, the "gluten-cells" become so separated from the true bran during their maceration in the intestinal contents that it is nearly, if not quite, impossible to recover them.

In order to satisfy ourselves regarding the digestibility of the cells of the fourth coat, we have subjected bran with its adherent "gluten-cells" to actual digestion by twelve well-nourished adults—six males and six females. These twelve persons were selected from a larger number by excluding all whose feces exhibited under microscopic examination any inefficiency in the amylolytic and proteolytic digestive ferments as evidenced by the presence of starch or muscle fiber in more than a minimal amount. Sources of error arising from individual peculiarities having been eliminated by the number of persons under observation, and the best conditions for digestion having been obtained, these persons then received daily for three days, in addition to their regular food, one ounce of thoroughly boiled bran. Their feces for the last two days of the treatment were submitted to close microscopical examination, with results so nearly uniform as not to require tabulation. In every case the number of "gluten-cells" present was more than sufficient to render a diagnosis of the food taken a matter of great ease. In two thirds of the cases no evidences of disintegration of any of the cells could be found upon repeated examination of many fields from each specimen. In four cases a small proportion (less than 10 per cent.) of the numerous cells examined showed evidences of having been affected by the digestive process, the cell contents having become lighter in color and less opaque. If, however, any true digestion of the cells had occurred, it is evident that many of these elements in different stages of disintegration would have been seen.

As a rule, we found that the several layers of the bran presented an appearance, not of having been digested, but simply of having been subjected to prolonged maceration. Thus, the

* "Amtsbl. d. Handl. u. Wer. d. Königr. Sachsen," 1868, No. 2.

† Hammersten, "Jahresber. d. Thierchemie," vol. iii, p. 207.

§ "Zeitschrift f. Biologie," vol. xix, 1883, p. 46.

three coats of the true bran, while entirely unchanged, were frequently found separated from each other. We had expected to find the fourth layer closely adherent to the third, as is the case in dry bran, but in the majority of specimens these two coats became separated, and occasionally large sheets of "gluten-cells," to all appearances perfectly normal, were seen. As a rule, however, that portion of the fecal mass representing the meal at which bran was taken* was found to contain these thick-walled cells in nearly every field.

A study of the nutritive relations of a given food may be approached from three sides: First, from that of the exact chemical composition of the food, a knowledge absolutely essential to any scientific scheme of diet; second, from that of the various excretions of the individual or animal upon the diet in question; and, third, from the more clinical standpoint of study of the effects exerted by a given diet upon the growth and nutritive processes of the organism under observation. After an examination of branny food in the light of the first two methods, we attempted its study by the third. To this end six young pigs of the same litter, and all in fair health, were weighed and placed under the same conditions in pairs, in three separate bins. Those in the first bin daily received bread especially made from whole wheat-flour, in amount corresponding to one fourth of a pound of dry bread each. To those in the second bin was given a corresponding amount of bread made from wheat whose three external coats only had been removed. The pigs in the third bin received the best white bread in amount corresponding to the standard above mentioned. A sufficient (fixed) quantity of water was given twice daily. The following table shows the weight of each pair at the beginning of the observation, and at the end of, respectively, ten and thirty-two days thereafter:

Bin.	Age.	Food.	Joint weight Mar. 6.	Joint weight Mar. 16.	Joint gain 10 days.	Joint weight Apr. 7.	Joint gain 32 days.
	weeks.		lbs.	lbs.	lbs.	lbs.	lbs.
I.	6	Bread from whole wheat	24.5	29.0	4.5	33.25	8.75
II.	6	Brown bread from deoricated wheat	24.75	28.25	3.5	34.50	9.75
III.	6	White bread	25.25	27.25	2.0	33.0	7.75

Comparison of these weights exhibits curious and apparently contradictory results, viz., that during the first ten days the gain was greatest in the pigs fed upon whole wheat bread, whereas, at the end of thirty-two days of such feeding, the gain was most pronounced in the pigs fed upon bread made from wheat whose three outer coats had been removed. The cause of this variation in results is not far to seek. At the commencement of the experiments the animals were small, and the food given was in each case more than sufficient to replace the waste in both the tissues and circulatory fluids. Even the pair fed upon bread containing the innutritious and waste-inducing bran digested and absorbed sufficient proteid matter to supply the needs of the tissues, and normal growth was also favored by the presence of bulky intestinal contents of a mechanically stimulating nature, and also by the nutritive salts which were present in this bread in larger amounts than in the others. On the other hand, at the end of the thirty-two days the animals had notably increased in size; the food given was then barely sufficient for the needs of the economy, and any conditions im-

peding its complete digestion and absorption produced a notable effect upon the rate of growth of these young animals.

It must be borne in mind that these experiments relate only to the value of the different breads when taken alone to the exclusion of other foods. The experiments of Rubner, before cited, leave no doubt that a white bread contains more assimilable nutriment than one made from the whole wheat does, but this does not render it a desirable food-stuff for exclusive use. On the contrary, a weaned but still quite young omnivorous mammal thrives better upon an exclusive diet of bran bread than on white, and, presumably, because the earthy and alkaline salts are present in greater abundance in the former, and also because the indigestible constituents tend to give to the intestinal contents that bulk and consistence which are essential to the hygiene of the digestive tract. But, as has been shown by Edward Smith and others, the branny scales are needlessly irritating, and unduly hasten the passage of food* but partially digested. The end which popular hygiene attempts to effect by the retention of bran in breadstuffs can be better attained by other means. Thus, the nutritive salts of food so frequently lost in ordinary methods of preparation are readily restored by the concentration of the liquor in which meats and vegetables are cooked into a soup stock, as is practiced in almost every French kitchen. Again, the various fresh green vegetables used as salads yield in abundance these inorganic food-stuffs the presence of which we have seen is indispensable to normal tissue activity. A further advantage of these and other succulent vegetables lies in the fact that their cellulose, while efficient in giving proper bulk and consistence to the stools, is, as compared with bran scales, soft and uniritating to the digestive tract.

From the facts, old and new, which have been presented, the following deductions appear to us justifiable:

I. The carbohydrates of bran are digested by man to but a slight degree.

II. The nutritive salts of the wheat grain are contained chiefly in the bran, and, therefore, when bread is eaten to the exclusion of other foods, the kinds of bread which contain these elements are the more valuable. When, however, as is usually the case, bread is used as an adjunct to other foods which contain the inorganic nutritive elements, a white bread offers, weight for weight, more available food than does one containing bran.

III. That by far the major portion of the gluten of wheat exists in the central four fifths of the grain, entirely independent of the cells of the fourth bran layer (the so-called "gluten-cells"). Further, that the cells last named, even when thoroughly cooked, are little if at all affected by passage through the digestive tract of the healthy adult.

IV. That in an ordinary mixed diet the retention of bran in flour is a false economy, as its presence so quickens peristaltic action as to prevent the complete digestion and absorption, not only of the proteids present in the branny food, but also of other food-stuffs ingested at the same time.

V. That, inasmuch as in the bran of wheat as ordinarily roughly removed there is adherent a noteworthy amount of the true gluten of the endosperm, any process which in the production of wheaten flour should remove simply the three cortical protective layers of the grain would yield a flour at once cheaper and more nutritious than that ordinarily used.

* We did not find it needful to give with the bran any coloring matter to differentiate in the feces the meal at which it was taken, as the scales of bran were always a sufficient index. When requisite, such differentiation may readily be obtained by the method of Cramer ("Zeitschr. f. physiol. Chem.," vol. vi, p. 354), or that of Rubner (*loc. cit.*).

* An observation worthy of mention in this connection is that of Rubner, who finds that, while the presence of much woody fiber and harder cellulose in the intestinal contents induces the passage of stools containing an excess of undigested proteid foods, the absorption of fats under the same conditions is not materially affected.

Lectures and Addresses.

THE CARTWRIGHT LECTURES

ON

METHODS OF STUDYING THE BRAIN.

DELIVERED BEFORE THE ALUMNI ASSOCIATION OF THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK, FEBRUARY 2, 4, AND 6, 1884.

By BURT G. WILDER, M. D.,

PROFESSOR OF PHYSIOLOGY, COMPARATIVE ANATOMY, AND ZOOLOGY IN CORNELL UNIVERSITY, AND OF PHYSIOLOGY IN THE MEDICAL SCHOOL OF MAINE.

LECTURE III, PART II.

(Continued from Vol. XXXIX, page 656.)

F. Anatomical figures should be placed so as to be most readily understood and instructively compared. In comparing pictures of two or more houses, ships, or stoves, the architect, the ship-builder, or dealer places them in such positions with regard to one another and his own eyes as may minimize the effort at mental transposition. If asked the principle on which he acts, he will probably say that no principle is needed; that he simply follows nature, experience, and common sense.

With few exceptions, it seems to be reserved for those whose business is the contemplation of natural objects, who are credited with more than the average degree of intelligence, and who have at command the recorded experience of centuries, to disregard a matter whose importance is equaled only by its simplicity.

Even where, as in the "Poissons fossiles" of the elder Agassiz (B), and in Huguenin's "Centres nerveux" the representations of laterad or mesad surfaces are uniformly placed (in the one case with the head toward the left and in the other toward the right), the desirability of maintaining such uniformity is not distinctly expressed. In most works on comparative anatomy there is an utter absence of system, and for the most part this applies to Quain and Gray, although the former sets a good example in respect to all the figures including the terma ("lamina cinerea"), 258, 279, 292, 303, 319. Seldom indeed are symmetrical figures placed otherwise than with the meson coinciding with that of the observer, but even this is less likely to confuse than the apposition of transections of a subcylindrical mass like the myelon, with the dorsum above in the one and below in the other, as in a recent number of this journal.

The prevalent carelessness in this regard may be attributed to three sources: *a*, The still too common idea that illustrations are of secondary importance; *b*, the fact that most figures have been copied, and thus placed without regularity as in the original; *c*, some time and trouble are required to reverse them.

The desirability of observing some uniformity in the position of anatomical figures was first impressed upon me twelve years ago in the effort to determine the fissural homologies among the carnivora, and in 1873 I adopted and suggested the plan of placing all the cephalad ends toward the left (17; 11, 217, Pl. 1-5; 18, Figs. 1-8).

Since most of the fissures usually appear to the best advantage from the side, the unnaturalness and inconvenience of the application of this rule to symmetrical figures were less apparent at that time, but were freely admitted in later publications (14, 544, 545; W. & G., 31).

Definitions.—Before stating the general rules as to the position of figures which are followed in the Anatomical Laboratory of Cornell University, it may be well to define a few new or little-used terms, which are employed for the sake of brevity and accuracy. The words are arranged rather in logical order than alphabetically.

FIG. 57.—SIX DIAGRAMS REPRESENTING CARDINAL ASPECTS AND SECTIONS OF A LIMBLESS VERTEBRATE. The boundaries of the head, trunk, and tail are indicated by constrictions. The limbs are omitted as involving needless complication. The eyes (not named) serve to indicate the cephalad end and the dorsad aspect. The heart, *c*, lies mostly sinistrad of the meson, as in mammals, and is seen to be in the sinistral-cephalo-ventrad eighth, whether of the body as a whole, or of the trunk alone. In the transections C, F, the right side is distinguished by a notch.

ABBREVIATIONS: *a*, axon, the body-axis; *c*, cardia, the heart; *dms*, dorsomeson, the dorsal margin of the meson or mesal plane; *e*, enteron, the alimentary canal; *n*, mouth; *ms*, meson, plana mesalis; *n*, neuron, axis neuralis, the cerebro-spinal axis or myelencephalon; *v*, vent or anus; *vms*, ventrimeson, the ventral margin of the meson.

A, sinistral aspect, or left side.

B, mesad aspect of the right half, after medisection (mesal hemisection).

C, dorsum, or dorsad aspect. The eyes are shown but not named. The straight line is the meson, and the heart is represented as if the body were transparent.

D, caudad aspect after dorso-ventral transection at the heart.

E, venter, or ventrad aspect. The meson and heart are as in C, but the latter, of course, is reversed in position on the page. Instead of the eyes, the mouth and vent appear.

F, caudad aspect after dorso-ventral transection at the heart. As compared with D, in respect to position on the page, there is not only dextro-sinistral but dorso-ventral inversion.

A and B are antimesal figures. C, D, E, and F are symmesal.

In the accompanying diagrams an entire animal is shown rather than the brain, because the outlines are simpler and more familiar, and the several regions are more readily recognized. No particular species is intended.

Axon.—The mesal, longitudinal, skeletal axis, represented in *Branchiostoma* and embryos by a membrano-gelatinous notochord, and in most adult vertebrates by the cartilaginous or osseous vertebral centra and basis crani.

Enteron.—The alimentary canal, lying ventrad of the axon.

Neuron.—The mesal nervous axis, myelencephalon, or axis cerebro-spinalis, lying dorsad of the axon.

Meson.—The ideal plane of separation or junction of the right and left halves of the vertebrate body; the mesium, plana mesalis, middle or median plane.

Dorsimeson.—The dorsal margin of the meson; the dorsal median line.

Ventrimeson.—The ventral margin of the meson; the ventral median line.

Picture-plane.—The plane or surface on which an object is, or is supposed to be, projected or represented; the perspective-plane.

Symmesal.—Having the meson parallel with the picture-plane, or forming therewith less than a midangle (45°) (Fig. 58, A, B; Fig. 59).

Antimesal.—Having the meson perpendicular to the picture-plane, or forming therewith an angle of more than a midangle (45°) (Fig. 58, C, D; Figs. 60, 61).

Direct position.—When the meson of the object is either parallel with or perpendicular to the picture-plane (Fig. 58, A, C).

FIG. 58.—DIAGRAMS ILLUSTRATING THE RELATIONS OF THE MESON TO THE PICTURE-PLANE.—The edge of the picture-plane, or plane of projection or perspective, is represented by the four divisions of the line $p-p$; the edge of the meson of the object by the lines $m-s$, 1-1, 2-2, 3-3, 4-4.

A, direct symmesal figure, in which the meson is parallel with the picture-plane.

B, oblique symmesal figure, in which the meson forms with the picture-plane an angle of less than 45° .

C, direct antimesal figure, in which the meson is perpendicular to the picture-plane.

D, oblique antimesal figure, in which the meson forms with the picture-plane an angle of more than 45° .

A and B are symmesal, C and D antimesal; A and C are direct, B and D are oblique.

Oblique position.—When the meson of the object is neither parallel with nor perpendicular to the picture-plane (Fig. 58, B, D).

Antitropic.*—Symmetrically related in position; similar, but pointing in opposite directions, so as to form a pair (Fig. 59, A, B).

Syntropic.—Similar and pointing in the same direction, so as to form a series (Fig. 59, B, C; Fig. 62, B, C, D).

Platetrope.—A part symmetrically related to another on the opposite side of the meson; lateral homologue; fellow of the opposite side. Examples: The right and left eyes, hands, etc.

Hemisection.—Division of the body at the meson or in a plane parallel therewith.

Longisection.—Division of the body in a plane parallel

with the axon, and thus longitudinal, but from side to side, thus at right angles to the meson and to hemisection-planes. (Suggested by Professor Gage.)

Transsection.—Division of the body in a dorso-ventral, dextro-sinistral plane, perpendicular to the meson; transverse section. The word is also applied to a subdivision of the body resulting from transsection, at two levels, or to either of the aspects so exposed.

Averted.—Having the head turned toward the top of the page (Fig. 60, A).

Adverted.—Having the head turned toward the bottom of the page (Fig. 61, A).

Cephalad.—Toward the head; used adverbially of direction, and adjectively as well as adverbially of relative position.*

Caudad, dextrad, sinistrad, dorsad, ventrad, mesad, and laterad.—Adverbs and adjectives signifying, respectively, toward the tail, the right, the left, the back, the belly, the meson, and either side.

General rules for the position of figures.—The following rules are based upon a consideration of (a) the natural attitudes of animals and men; (b) the lateral division of the vertebrate body into a right and left half; (c) its serial subdivision into several segments (metameres or somatomes); (d) the current view as to the normal position of the body; (e) the natural and customary movements of the eyes and head; (f) the arguments, from custom and from the nature of things, for placing the head of an object toward the left; (g) the customary attitude of the head in examining and comparing objects; (h) the value of time to the naturalist; (i) the fact that mental operations, such as are required for the comparison of figures not properly coadjusted, occupy time and attention.

It should be understood that these are merely general rules; probably there is no one of them to which exceptions may not exist; but such exceptions should always have a well-defined reason, and not occur through inadvertence.

The rules are equally applicable, abstractly, to the objects themselves, but there are sometimes obstacles to their practical observance which appear to be well-nigh insuperable.†

1. Figures should be coadjusted so as to facilitate comparison with each other and with typical structures in normal positions.

2. The dorsum should be above.

3. Direct positions (Fig. 58, A, C) are to be preferred.

4. Antimesal figures (Fig. 58, C, D) should be so placed that, if direct (C), the meson of the figure is in the same plane as the meson of the observer.

5. With a single symmesal figure, the head should look sinistrad (Fig. 59, C).

6. In a syntropic series, whether horizontal or vertical (Fig. 59, B, C), the head should be toward the left.

* Heretofore the adjective used has been *cephalic*. The reasons for the change will be presented farther on.

† For example, it is desirable to have some alcoholic preparations or entire examples of fishes, etc., in the horizontal position, so as to be readily comparable with their skeletons. The leakage of alcohol may be nearly or quite prevented by the use of vaseline, as recommended by Professor Gage and myself (W. and G., I).

* For this and the two following terms, see my paper on "Intermembral Homologies" (10, 30, 38, 35).

7. Antitropic figures should be arranged in pairs, and upon the same horizontal line (Fig. 59, A, B).

FIG. 59.—TWO WAYS OF PLACING ANTIMESAL FIGURES FOR COMPARISON. A, B, the right and left sides of the same object, or of two different objects, antitropically placed. B, C, the left sides of two objects, syntropically placed, one above the other.

8. When the dorsum and venter are placed side by side, the latter should be at the left if the heads are averted, and at the right if they are adverted. In both cases the object is supposed to be rotated on its axon so as to expose the left side in the interval between the dorsal and ventral exposures.

FIG. 60.

FIG. 61.

FIG. 60.—A, dorsum; B, C, D, a series of caudal surfaces, exposed at successive levels. The right and left in these figures coincide in position with those of the observer.

FIG. 61.—A, dorsum, the head toward the observer and the bottom of the page; B, C, D, cephalad surfaces exposed by transections at as many levels. As with the entire figure, the right and left of the transections are reversed as compared to those of the observer.

9. Transections of an antimesal object should form a vertical syntropic series. When the head is averted (Fig. 60),

FIG. 62.—LEFT ASPECT OF THE BODY (A), WITH TWO SERIES OF TRANSECTIONS. B, C, D, caudal aspects; E, F, G, cephalad aspects. In the former series the right and left of each figure correspond with those of the observer, who is supposed to be looking from the tail toward the head. In the latter, he looks in the opposite direction, and the right and left are reversed. In B and E the apex of the heart appears on the left of the meson, and in all the transections the right side is notched. This figure also illustrates the way of placing a series of three or more similar figures for comparison. When only two are to be compared, they may be placed antitropically, as in Fig. 63.

caudal surfaces will be shown; cephalad surfaces when the head is adverted (Fig. 61).

10. Transections of a symmesal object, if three or more, should form a horizontal syntropic series (Fig. 62). If caudal surfaces are shown, the right and left of each section will correspond with those of the observer (A, B, C); they will be opposite or reversed if cephalad surfaces are represented (D, E, F).

11. When transection-surfaces are naturally paired, like the opposite ends of a transection-piece (Fig. 63, C, D) or

FIG. 63.—TWO INSTRUCTIVE MODES OF PLACING FIGURES OF TRANSECTIONS FOR COMPARISON. In all, the right sides are designated by notches; in A and B the left sides also show the heart.

A, B, the apposed surfaces exposed by a transection at a single level.

The relations of the sections will be more apparent when compared with parts of Fig. 62.

A, B, the apposed surfaces exposed by a transection at a single level, as by the line 1-1 in Fig. 62. A is the caudal aspect of the cephalad portion, and B the cephalad aspect of the caudal portion. As mere surfaces or as microscopic sections they are identical, but, when cavities are exposed, the views in opposite directions are instructively complementary.

C, D, the apposed surfaces exposed by transections at two levels, leaving a mass with a cephalad aspect, C, and a caudal aspect, D. In Fig. 63, F is the cephalad end and D the caudal.

In Fig. 62 the figures form a syntropic series, while in Fig. 63 the apposed or opposed surfaces are in pairs, antitropically placed.

the apposed surfaces formed by a single transection-plane (A, B), they should be placed antitropically like two halves of the same object.

12. When figures in a series are to be compared, like the mesad aspects of hemiencephala (Lecture II, this journal, February 23d, Figs. 40-43), one or more may be reversed from the position they would naturally have so as to conform with the majority, or with the rule of having the cephalad end toward the left.

13. Portions of transections should include a little more than the half, so as to show the location of the meson (Fig. 64).

FIG. 64.—The figures are intended to be identical, excepting for the two degrees of reduction in B and C.

The figure illustrates the way in which a symmesal object which is symmetrical may be represented in part and yet adequately, thus affording room for names or abbreviations.

With special parts should be included, at least in outline, enough of the entire organ or animal to indicate their position therein.

G. The full technical names of parts should be given, if possible. From the purely artistic point of view, any extraneous line upon a picture is a disfigurement. But if it

be once admitted that the primary object of an anatomical drawing is to convey accurate information, then, unless the shaded figure can be duplicated in an outline (as in Tiedemann, B, and Vicq d'Azyr), there should be no sacrifice of the essential to the accessory.

It may be a question whether the names should be upon the parts (as in Gray, Smith, etc.) or at the side of the figure, and connected with the parts by lines (Gegenbaur, D). Upon the whole, the latter method seems preferable, especially if the technical names are used.

H. Abbreviations should represent technical terms, be uniform throughout the work, and be placed at the sides of the figure.

Four methods of designating parts by abbreviations have been employed: 1, By numbers and insignificant and ununiform letters, which may or may not be explained in the text (Owen); 2, by insignificant characters, uniform only in part, and explained at a distance from the figure (Reichert); 3, by uniform and significant, but partly vernacular, abbreviations (Parker, 25); 4, by uniform technical abbreviations (Wilder, 14, and W. and G.). In the last-named work an effort was made, in most cases, to place the abbreviations upon the parts; to do this neatly and clearly is difficult if not impossible, and the authors believe that it is better, usually, to place the abbreviations at the sides of the figure, and to connect them with the parts by dotted lines, although continuous lines are employed by Gegenbaur (D) and Reichert.

The point as to whether abbreviations should be of technical or vernacular terms is involved in the larger question respecting the exclusive employment of technical terms, and will be considered farther on.

The advantages of uniformity in the use of abbreviations are obvious, but it is by no means easy to avoid the chance of ambiguity. Where uniformity is not attempted, care should at least be taken to avoid the use of the same abbreviation for the names of parts which are liable to be taken for one another. For example, in Schwalbe's two representations of the lateral aspect of the mesen and adjacent parts (Figs. 280, 281), not only are opposite sides shown for no good reason, with some differences of detail which are puzzling rather than instructive, not only is the pons designated in one by *p* and in the other by *po*, and the Tractus opticus by *to* in one and *tr.o* in the other, but the letters *tp* stand for the *tenia pontis* in Fig. 280, and in Fig. 281 the *tractus peduncularis transversus* (cimbia). Since these parts are similar in general appearance and direction, and only one appears in each figure, it is doubtful whether any but the most expert anatomist, thoroughly familiar with this somewhat obscure region, could escape at least a temporary misapprehension.

I. Abbreviations should be explained in alphabetical order. The "practical" business man would exclaim, "Of course, how else should they be?" An "unscientific" child would adopt the alphabetical order with letters as he would the order of notation with numbers. But the super-scientific writer, especially if he be a German, scruples not to save a few moments of his own time at the expense of others, by giving the verbal equivalents of ten (Huxley, Fig. 19), fifteen

(Balfour, ii, Fig. 271), twenty (Quain, Fig. 263), twenty-five (Schwalbe, Fig. 279), or even forty (Meynert [Stricker], Fig. 253) abbreviations, either in no recognizable order at all, or as they occur upon the figure. The time wasted by each consulter of the figure (not to mention the effect of just indignation) would nearly equal what it would have cost the author to place the abbreviations in alphabetical sequence.

(To be concluded.)

Original Communications.

RETRO-PHARYNGEAL ABSCESS.*

By JOHN O. ROE, M. D.,
ROCHESTER, N. Y.

THROUGHOUT the body, organs which require a large amount of motion upon each other in the performance of their respective functions are connected by, and the space between them is filled with, loose areolar connective tissue. It is this space that affords the most favorable location for the formation of abscess, the deposit or the collection of the products of broken-down degenerate tissue.

The causes determining the location of abscess in these spaces are:

1. The low degree of vitality of this tissue and the readiness with which it breaks down when attacked by disease.
2. The looseness of this tissue and the ease with which it can be pushed aside or displaced by the accumulations of inflammatory products originating in neighboring parts.

The space behind the pharynx and in front of the vertebral column, which Henke† designates the "retro-visceral spaces of the neck," is filled with a layer of this loose connective tissue to facilitate the movements of the pharynx over the spinal column, necessitated in the act of deglutition, and it is the accumulation of purulent material in this space which we denominate from its location retro-pharyngeal or post-pharyngeal abscess, or, according to König,‡ "retro-visceral abscess of the neck."

Post-pharyngeal or retro-pharyngeal abscesses are divided into two main classes: 1. Those that originate in the soft parts; and, 2. Those that originate in disease of the spinal column; or they may be divided, according to König,* into acute idiopathic and chronic symptomatic.

According to their clinical manifestation or causation, they can be again divided into—

1. Idiopathic.
2. Secondary from burrowing of pus from abscess in the neck.

* Read before the American Laryngological Association, May 12, 1884.

† These visceral spaces of the neck are admirably illustrated by Henke in his "Beiträge zur Anatomie des Menschen mit Beziehung auf Bewegung," 1 Heft, S. 12-14, the drawings for which were made from sections of frozen bodies, the visceral spaces of the neck having been previously injected with glue.

‡ Pitha u. Billroth, "Chirurgie," Bd. iii, 1 Abth., 4 Liefg., S. 8.

* Op. cit., S. 11.

3. Secondary from burrowing of pus from cervical spondylitis.

4. From phlegmonous inflammation following measles, scarlet fever, diphtheria, tonsillitis, etc.

5. Metastatic in septicæmia and following local inflammation or the formation of pus in other parts of the body.

6. Traumatic.*

The views formerly entertained by writers as to the etiology of idiopathic retro-pharyngeal abscess in children have been greatly modified by the more recent and minute study of the glandular structures of this region.

Some writers, as Barmhuger,† Vogel,‡ and Niemeyer,§ believe with Dupuytren|| that abscesses in the posterior portion of the pharynx are nearly always symptomatic of caries of the basilar apophysis of the occipital or of the transverse apophysis or body of the upper cervical vertebrae. And Steiner^ also says that retro-pharyngeal abscess is rarely idiopathic or caused by suppurative of the retro-pharyngeal glands, but is more frequently due to caries of the vertebrae.

Bókai,¶ who has given this subject more careful and elaborate study than any other observer, considered, in his first article, that they mainly arose from a phlegmonous inflammation of the connective tissue, but, since Roustan‡ and Gautier§ pointed out the connection between lymphadenitis and retro-pharyngeal abscess, Bókai's later investigations and observations have shown him that the idiopathic form is due to suppurative of the post-pharyngeal glands.

This view has since been confirmed by Schmitz,‡ Just,**, Albert,†† and most other recent observers.

The relation between idiopathic retro-pharyngeal abscess and retro-pharyngeal lymphadenitis is readily shown by the study of the glandular structure of this region. These glands are the compound follicular and the racemose. The former are quite numerous beneath the mucous membrane throughout the pharynx, while the latter are located mostly in the upper part, forming a thick layer across the back part of the fauces between the two Eustachian tubes (Gray).

In addition to these glands, Heiberg-Hjalmar, of Christiania,‡‡ describes another open system of canals, from which, however, the lymphatic vessels can not be injected.

The lymphatic glands of this region are described by

* This division is mainly that made by Bókai, and formulated by him from his large number of clinical observations.

Edward Simon* as communicating with vessels which run in a sort of furrow between the forward end of the Eustachian tubes and the rear end of the turbinated bones. Here they form a small network from which two or three trunks of about one millimetre in diameter arise.

These run obliquely backward and outward, one of them terminating in a gland in front of the vertebrae.

These glands are located one on each side of the median line between the constrictor pharyngeus superior and the aponeurosis of the pre-vertebral muscles. Occasionally an additional gland is found.

The vasa afferentia of these glands arise in three or four main trunks from the mucous membrane of the upper and lateral surfaces of the pharynx, and from the upper surface of the soft palate.

The vasa efferentia pass into the glands situated to the outer side of and somewhat below the tonsils, where they meet the large number of the lymphatics of the tongue.† In case only one gland exists, it is generally found to the right side. After the third year of life they generally disappear altogether.

The connection between idiopathic retro-pharyngeal abscess and retro-pharyngeal lymphadenitis is demonstrated very clearly by the complete records so carefully kept by Bókai of all the cases of retro-pharyngeal abscess and retro-pharyngeal lymphadenitis occurring in the Children's Hospital at Pesth during the twenty-six years from 1854 to 1880.

During this period there occurred 204 cases, 179 of which were of the idiopathic form; 7 were secondary to burrowing of pus from abscesses in the neck, 7 secondary to caries of the cervical vertebrae, 9 to scarlet fever, 1 to measles, 1 traumatic.

During this period there occurred 63 cases of retro-pharyngeal lymphadenitis which did not terminate in abscess. The connection between the location of the abscess and the normal location of these glands is also quite significant.

Of these 204 cases, 85 occurred on the right side, 78 occurred on the left side, 37 occurred in the middle, and in 4 the location not stated.

During the same period there were observed 63 cases of retro-pharyngeal lymphadenitis that did not terminate in suppurative. Of these, there were: On the right side, 33; on the left side, 21; in the middle, 4; location not stated, 5.

It is also to be seen from the table that these 267 cases, including the 63 cases of retro-pharyngeal lymphadenitis, occurred in 147,879 patients that were treated during the period from 1854 to 1880, indicating that the affection is by no means of frequent occurrence.

As will also be seen from the tables, the period of the greatest frequency, or almost exclusive occurrence, is during the first two years of life, and after three years of life, when these glands normally disappear, the idiopathic form is seldom seen.

Thus, of the 204 cases, 196 occurred during this period.

Another fact which points to the lymphatic glands as

* Schmidt's "Jahrb.," 107 B., S. 161.

† "Jahrbuch f. Kinderh.," n. F., 1872-'73, vi, S. 283.

the seat of idiopathic retro-pharyngeal abscess is the slow development of the abscess and its circumscribed condition. Phlegmonous inflammation of the connective tissue, and especially of the loose tissue found in the retro-pharyngeal space, runs a rapid course and ends in a few days in suppuration, whereas acute lymphadenitis runs its course slowly, and, as Schmitz* observes, spreads rapidly only after the enveloping membrane of the gland has become perforated.

ÆTIOLOGY.—All constitutional diseases that predispose to inflammation of the lymphatic glands in general play an important part in the production of retro-pharyngeal abscess. Of these, scrofula and hereditary syphilis stand at the head.

Scrofula is by far the most frequent cause of glandular enlargements, although many cases of syphilis in adults, as well as in children, are overlooked, their results being classed under the general and quite satisfying term scrofula.

Bókai† reports two cases in children directly caused by syphilis.

Cases are reported in adults the direct result of acquired syphilis. Thus, Edward Martin‡ reports a case in a man, forty-four years old, the result of syphilis contracted eighteen years before. Tertiary symptoms appeared, with swelling of the lymphatic glands of the neck on the right side, associated with suppuration of the middle ear and mastoid cells. The abscess occurred on the right side of the pharynx. After it was opened, pus could be squeezed out by pressure on the mastoid region. The patient recovered.

The most frequent exciting cause is exposure to sudden changes of temperature and the taking of colds, giving rise to attacks of rhinitis and inflammations about the fauces.

In this connection, the period of the year in which retro-pharyngeal abscess most frequently occurs is quite significant.

From Bókai's tables it is seen that it is most prevalent during the months of November, December, January, February, March, April, and May—months during which colds are also most prevalent.

There can be little doubt of the connection between chronic rhinitis in children and retro-pharyngeal abscess, for it is a well-known fact that enlargement of the lymphatic glands of the neck is almost always found in children suffering from snuffles, and the formation of abscess in lymphatic glands from the absorption of septic material into the lymphatic vessels is a very common occurrence.

Fraenkel* says: "It is not very uncommon for swelling of the glands to outlast the catarrh which caused it, and then it may remain as an independent affection, subject to further changes."

It is now believed that retro-pharyngeal abscess following scarlet fever, measles, erysipelas, and other affections attended with inflammations about the naso-pharyngeal cavity in children, is of the same nature as the idiopathic form, and is the result of disease set up in the glands from lymphatic absorption rather than from the formation of pus in the connective tissue as the direct result of the phlegmon.

In support of this view, Lewandowsky* says: "The presumption that these abscesses have really nothing to do with scarlatina, but are only accidental complications, may be rejected, leaving aside all other reasons, for the reason that the views entertained as to the pathogenesis of these abscesses also give a ready explanation of just why they should occur in scarlatina."

Of two cases of retro-pharyngeal abscess reported by Lewandowsky occurring after scarlet fever, in children aged seven and twelve months, he says: "While both cases in their general character were of a favorable nature, there existed a *violent inflammatory condition of the nose*, upon which I lay special stress as a cause of the retro-pharyngeal abscess. . . . To explain the retro-pharyngeal lymphadenitis by the angina does not appear to me admissible, because in both cases it was exceedingly mild."

Bókai also remarks that the cases reported by him as occurring in scarlet fever did not differ from the idiopathic form.

Surely violent phlegmons of the pharynx must rarely be the cause of retro-pharyngeal abscess, for, among the many cases seen by Bókai, not one was caused by diphtheria.

Suppuration in the tympanic cavity in children is pointed out by Wiel† as a not infrequent cause of retro-pharyngeal abscess. He reports a case in a child, nine months old, that died from secondary œdema of the larynx. On post-mortem, the suppuration in the ear was shown to have been the cause of the abscess.

Wiel quotes Koths (from his article on "Pharyngeal Diseases," in Gerhard's "Handbuch"), who says: "Retro-pharyngeal abscess is also found in inflammations of the middle ear."

Wiel also quotes from Korman: "Idiopathic retro-pharyngeal abscess arises from retro-pharyngeal lymphadenitis. These glandular inflammations are found in cases of inflammation of the mucous membrane of the mouth, pharynx, and ear."

In ten cases of otitis (mostly middle-ear catarrh) Wiel found glandular swellings.

Bókai speaks of the connection between these abscesses and inflammations of the meatus, but does not seem to recognize cause and effect between them.

This relation between the two is an important observation, but is by no means the only ground on which to urge the necessity of prompt and careful attention to all cases of suppuration of the middle ear in children.

The symptomatic indications in this affection are only of value to direct our attention to the seat of the affection, for, as Albert‡ remarks, "the main trouble is that pharyngeal abscess is not thought of, and the patient is treated for angina."

The general symptoms attending this affection—as dysphagia or aphagia, dyspnœa, dysphonia, cough, swelling of the neck externally, etc.—may resemble in many essential particulars those caused by croup, œdema of the larynx,

* *Loc. cit.*

‡ *Loc. cit.*

enlarged tonsils, or a foreign body in the larynx, but a thorough examination of the throat, which should always be made in all such affections, will at once reveal the true nature of the difficulty.

The most constant symptom is difficulty in swallowing, although exceptions to this rule occasionally occur.

Pepper* reports the case of a child, thirty-two months old, who had a retro-pharyngeal abscess occurring six weeks after recovery from diphtheria.

In this case the swelling of the pharynx produced great dyspnoea, but no hindrance to swallowing.

It should be noted, however, that in those cases where the abscess is so deep seated that it can not be seen or felt, but produces dysphagia and dyspnoea by compressing the œsophagus and trachea, the voice has a peculiarly shrill tone like a duck's voice, which is of marked diagnostic significance, as Duparcque† has pointed out.

The position of the head is also of special significance. In all these cases there is a peculiar stiffness of the neck resembling rheumatic torticollis, the head being thrown to the unaffected side. This is so characteristic that Albert‡ says he rarely fails of diagnosing retro-pharyngeal abscess on first glancing at the child.

Tenderness over the spine and a kyphotic prominence of some one of the spinous processes are important to note as indicative of caries of the vertebræ.

In the study of retro-pharyngeal abscess we see that the idiopathic form occurs in children, and nearly always when they are under two years of age, and that those cases arising from other causes are rarely seen in children under three years of age, although caries of the vertebræ arising from various causes may occur at any age.

Those originating from the burrowing of pus from neighboring parts, from traumatic injury, from tonsillitis, or metastatically, occur indifferently in adults and young people.

Nélaton* says that suppuration in the region of the perinæum frequently leads to the formation of pus in distant organs, particularly in the neck.

In illustration of this metastatic origin, he reports a case of retro-pharyngeal abscess, the result of or associated with traumatic stricture which led to perineal inflammation and suppuration from extravasation of urine.

A case of retro-pharyngeal abscess following quinsy has come under my own observation.

A student, aged twenty years, was out at a late class supper, ate very heartily, and during the evening took cold. The next day he was sick with diarrhœa, headache, and severe sore throat. He grew rapidly worse, and was treated for ulcerated sore throat. The second day afterward his neck was very much swollen, mostly on the right side. He was hoarse, and spat blood from what proved to be an abscess in the tonsil that had opened spontaneously. When I first saw him, on the fourth day, the surrounding parts were much swollen, as was also the pharynx, which bulged forward on the right side. A digital examination showed this swelling to be a retro-pharyngeal abscess. I at once opened it, and much bloody, purulent matter

was discharged. Soon afterward the tract of the abscess began to extend downward quite rapidly, until it had dissected down behind the cervical portion of the œsophagus and become retro-œsophageal.

The discharge from it was very copious, pus in large quantities being thrown out. At times the discharge was so profuse as to nearly suffocate him. On breathing, it sounded as if the air passed through a quantity of soap-suds. Temperature 103° F., pulse 120. Several physicians saw him with me; but, in spite of all that could be done, he continued to grow worse, the bloody and purulent discharge increased, he became rapidly weaker, and died from exhaustion and increasing suffocation on the third day after I saw him. No post-mortem, I regret to say, was permitted.

The two following cases of retro-pharyngeal abscess have also come under my observation. The first was idiopathic, and of serofulous origin; the second followed scarlet fever; but both could be quite directly traced to nasal disease.

On the evening of February 12, 1884, by the advice of the family physician, I was requested to see a child, nine months old, who was nearly suffocated from what was thought to be diphtheritic croup. I found the child with extreme dyspnoea, evidently caused by obstruction in the throat. The head was thrown to the right side, and there was a marked swelling on the left side of the neck and behind the angle of the jaw. She was unable to cry or to make a laryngeal sound; but there was entire absence of the systemic inflammatory disturbance which attends diphtheritic croup.

Upon examination of the throat, the pharyngeal wall, mainly on the right side, was seen markedly bulging forward. It had the appearance of a tumor, and filled the lower pharynx, nearly cutting off respiration. The neck on the left side, externally, was also greatly swollen from the clavicle to the ear. The swelling in the throat had the appearance of a hard tumor, but to the touch with the finger it was soft and fluctuating, indicating at once its nature.

Being fearful lest, on opening the abscess, some pus should be sucked into the larynx of the child and, in her nearly moribund condition, strangle her, I took the precaution to make a very small incision into the abscess, which allowed its contents to escape very slowly, and, by at once putting her head downward and forward, and holding it there until sufficient pus had escaped to relieve the dyspnoea, all danger was avoided.

Afterward I enlarged the incision to allow free escape of the entire contents of the sac. The child was at once relieved. She took nourishment freely, which she was unable to do at all before.

There has been no tendency to recurrence of the abscess, and the child was improved greatly in its general condition. For a few days afterward, however, she had some embarrassment to respiration, owing to obstruction of the nostrils from snuffles or a subacute catarrhal condition of the passages, from which she had been suffering for several weeks previous to the occurrence of the abscess.

The child from birth had been weak, cachectic, and serofulous, with more or less enlargement of the cervical lymphatic glands. When three months old she had measles, from which she slowly recovered. For two months after she continued to have a succession of bullæ, or fever boils, as they were called, about the neck, arms, and back. They were of about the size of a cent, would fill with pus, and in three or four days break and dry up, new ones forming around the old ones. Sometimes the old ones would refill.

When five months old the child had summer diarrhœa, and convulsions, sometimes three or four a day.

* "Philadelphia Medical Times," Sept. 25, 1875, vol. v, p. 817.

† Schmidt's "Jahrbücher," Bd. v, supplement, p. 191.

‡ *Op. cit.*, p. 356.

* "All. Wien. med. Zeitung," 1862, Bd. vii, S. 43.

Five weeks before I saw her, her cervical lymphatics became swollen, and she began to have a severe cough, like whooping-cough. Three weeks later she began to have some dyspnoea and dysphagia, which gradually increased until I saw her.

(To be concluded.)

A WINTER IN COLORADO.

By EDWARD T. ELY, M.D.,

NEW YORK.

IN the climatic treatment of consumption, cold, elevated regions are certainly now in fashion with the medical profession, and bid fair to remain so. The interest taken in them leads me to give a few of my own impressions of a winter in Colorado. Many places are now open to invalids in Colorado and New Mexico, and each offers its own advantages, especially where business and a permanent residence are concerned. Many eastern physicians think that New Mexico is much warmer than Colorado—that it is something between Colorado and Florida—but this is not true of its chief health-stations—Las Vegas and Santa Fé. Their winter climate is cold, differing very little from that of Colorado. Where a moderately high altitude and a cold, dry climate are desired, I believe there is at present no available place in the world that offers more attractions for a winter's sojourn than Colorado Springs, and it is to this town that my observations have been mostly confined. The beneficial effect of Colorado climate on pulmonary disease is incontestably proved by hundreds of cases. Exactly how this effect is produced is not perfectly plain. Great stress is laid by some writers upon altitude and diminished oxygen, and the action of these conditions upon the human system is explained glibly enough. There is, however, much theorizing that does not rest, so far as I am aware, on any sufficient basis of accurately observed clinical facts. Some of it is opposed to the elementary laws of physics, and is sheer nonsense. Even the laity have grown very learned upon these matters, and some of the conversation which one overhears while sitting about the stove of a high-altitude boarding-house is extremely entertaining. If rarefied air can do all that some of these philosophers claim for it, it is not strange that it should stretch the poor asthmatic's bronchioles until they are glad to give up the fight, or that it should "open up" the consumptive's air-cells so thoroughly that the bacilli are glad to move on to more quiet lodgings. I have heard one man say that the altitude had forced him to give up his sponge-baths, and another once explained to me how his cowboy-hat, which felt easy on his head under the shadow of Pike's Peak, would be so unendurably heavy at sea-level that he would not care to take it home with him!

Probably the most important factor here, and everywhere else, relates to the number of days in the year when the patient in question can enjoy sunshine, pure air, and a life out of doors. The number of such days in Colorado is unquestionably large, although considerable misapprehension exists regarding them. It is a common boast here that there is not a day in the year when one can't get out of doors. This may be true, but the getting out often amounts

only to half an hour on the porch, or a walk to the post-office, and such achievements are not of much account where the question concerns an out-door life. It is customary with writers on Colorado to count the forty-odd cloudy days in a year, which is the average shown by the Signal Service reports, as days when an invalid may be housed by bad weather, and to represent that on the remainder—say three hundred and twenty days—an out-door life is both practicable and agreeable. Such a statement is true, I think, only for those who are quite strong, like some patients in the earliest stages of consumption. Many who come here will be compelled to spend a larger number of days in the house, and on many of the remaining days they will find little inducement to going out, and will shirk it. I have known several invalids this winter who would not be called very feeble, but who have been practically housed from sixty to ninety days, and who have by no means led what I should call an out-door life during the rest of the time. Concerning such a matter, testimony that does not rest on a written record is of little value. For instance, I asked a lady at the hotel how many days she had been shut in by bad weather during the past winter. "Not more than six," was her enthusiastic reply, and yet eighty would be nearer the truth, as she readily admitted when I showed her the result of my own written memoranda. Much of the testimony about climate derived from talking with invalids is as untrustworthy as hers was.

In much that has been written about Colorado climate there has been, to say the least, a *suppressio veri*, and it is not surprising that people so rarely find the weather here to be what they had expected. "Perpetual sunshine" is a phrase so often used that invalids come here really expecting to find it. "Day after day," says one writer, "until weeks merge into months, the sun rises in an almost cloudless east and sets in a cloudless west."* Such an unqualified statement is misleading; even the local weather reports, which more than do justice to the sunshine, rarely show a month without cloudy days. So with the dryness of the atmosphere. Invalids are told to leave their umbrellas at home, and to bring ointments to anoint their noses when the dryness shall have made them sore. If they trust the statement that "there is absolutely no rain after the 1st of September," they may sometimes get a wetting; and, if they anticipate much trouble with their noses, they are likely to be happily disappointed. That iron will not rust, that dead animals do not stink, and that there is no dew-fall, are stock statements, and all untrue. Nor is the snow always licked up by the dry air in the mysterious way so often pictured to us. It does disappear very rapidly, as a rule; but a visitor must not be surprised if he occasionally encounters mud and slush, and sees the snow going the way of all eastern snow. That "it is never muddy here for more than a few hours" is not strictly true. I have seen here genuine fogs, very dense, and lasting sometimes all day. But fogs are uncommon and scarcely worth mentioning, were not their existence so often denied. Then, too, there are the winds, which are surely both disagreeable and objectionable. The efforts of the pamphleteers to prove that this is not a windy place are

* "Colorado Springs and Manitou," Edward Roberts.

more amusing than convincing. The tables of "comparative velocity," etc., which will make the sick man believe that there is only just enough wind here to "blow away the impurities," have yet to be compiled. Many a clear, sunshiny day is so spoiled by cold wind as to be lost to the invalid, and the winter days when there is not more wind than is agreeable are decidedly in the minority. It is difficult to believe that a climate like this, *minus* the winds, would not be a better one. Dr. Solly's statement that "the air is particularly calm in winter" seems almost like a joke.* Dr. Fisk's tables give an average of only twelve calm days in the whole year in Denver. His tables also show that the prevalent wind here is from the south, and he lays stress upon "a prevailing balmy and salubrious south wind" as one of the advantages. "The south wind," he says, "is the salubrious one for the eastern slope of the Rocky Mountains in Colorado, and our table shows that to be the balmy wind that blows."† The fact is, I believe, that the south wind here is one of the most chilly and disagreeable of all, and that, if any wind deserves the name of *balmy*, it is that which comes from the west.

The system of recording clear, fair, and cloudy days, which is in vogue here and at other resorts, is not entirely satisfactory. Observations of the area of the sky covered by cloud are made three times daily—at 7 A. M., 2 P. M., and 9 P. M.—and the mean of these is taken. If the result shows the sky clouded less than $\frac{3}{10}$, the day is clear; if from $\frac{3}{10}$ to $\frac{7}{10}$, fair; if $\frac{7}{10}$ or more, cloudy. Now, a day that is clear at 7 A. M. and 9 P. M., and cloudy all the rest of the time, would thus be set down as a fair day; so would a day that was cloudy at 7 A. M. and 9 P. M., and clear during all the interval. Moreover, a day might be partially cloudy just at the time of the observations and otherwise clear, or *vice versa*. Or, the sky might be cloudy $\frac{3}{10}$ or more throughout the day, and yet the clouds be so distributed as to interfere but little with the sunshine. Again, no account is made of the *density* of the clouds. The sky may be cloudy and yet the cloud be so thin that the sun is scarcely obscured at all by it. Such a method of observing may be all that is desired for scientific purposes, and may give a fair estimate of the amount of cloudiness during each twenty-four hours; but I doubt if it accurately expresses the number of hours of sunshine available for the invalid, and this is what invalids and their doctors most desire to know. A person trying to form an idea of how much time he will be able to spend out of doors in a given locality has comparatively little interest in observations upon the condition of the sky during the hours when he is in bed, however important they may be in estimating the character of the climate as a whole. I think it would be useful if visitors would make supplementary observations on such a plan as the following: Consider the period from 9 A. M. to sunset as the invalid's day; if during this period there is constant sunshine, call the day clear; if less than two hours of sunshine, cloudy; otherwise, fair; and make special mention of wind, storms, days when the sun is not seen at all, etc. I think that such a

classification is eminently just to the climate, and that it would perhaps be a more useful guide, for some purposes, than the statistics now provided. For the invalid's uses, a day that has less than two hours of sunshine between breakfast and sundown is certainly not "fair," whatever the Signal Service Bureau may say about it. The method just proposed might alter somewhat the present showing of clear and cloudy days in Colorado.

Many things said above about the weather may seem trifling, and, in one sense, they are, but still it is necessary to consider just such small matters in order to form an accurate estimate of the climatic conditions of this or any other health-resort. The wild ideas which people coming here entertain about the climate, and the number of wholly unsuitable cases sent here by reputable doctors, show what erroneous opinions have spread abroad. Visitors may fairly expect to find a remarkably dry atmosphere, a rainless winter, a large amount of clear weather, a very warm sunshine, and the purest of air, all of which will constitute, not a paradise, but something far better than prevails over the greater part of our country. They must not expect to realize all that is described by enthusiasts and by those having a pecuniary interest in "booming" the State. They will find that the amount of time which they can spend out of doors will depend somewhat upon their ability to take active exercise and to resist cold, and they will encounter severe storms and a goodly number of "exceptional" days when they will revile the wind, the dust, the great changes of temperature, the low-hanging clouds, and will avow that the weather is no better than at home! They will find a winter climate by no means so seductive as that of more southern latitudes, but they will experience some of the finest winter days imaginable, and a sunshine so warm that I have been able to sit out in it comfortably when the mercury was only 2° above zero. Moreover, they can stay here, if it suits them, the year round without the necessity of fleeing before a spring thaw or a dangerous summer heat.

My winter's experience may be of some slight value in showing what can be accomplished here in the way of outdoor life by a person too feeble to take any vigorous exercise, such as horseback-riding, walking, or climbing—a person, in short, whose only resources are sitting on a piazza or driving. Asking pardon for so many personal details, I will say that I am less sensitive to cold than the average, and enjoy a remarkable immunity from taking cold. During the past winter I have scarcely spent an hour in-doors (except at meal-time) when the weather allowed me to be out, having even taken advantage of the hours before breakfast. I have had the use of the largest and most sheltered piazzas in town. I have been out far more than any other invalid in the hotel, although nearly all were stronger than I. I have sat out many days when not only no other invalid in the hotel but not even my well friends were able to keep me company on account of the cold. I have often sat out, bundled up in ulster and steamer-rug, when there was no pleasure in it whatever except that which comes from the consciousness of doing one's duty! I have been able to drive in very cold winds and in snow-storms without any apparent harm. I therefore infer that I may be taken

* "Health Resorts of Colorado Springs and Manitou," S. Edwin Solly.

† "Analysis of Signal Service Statistics," Dr. Samuel A. Fisk.

to represent the outside limit of what an invalid, in my condition regarding exercise, can do in the way of out-door life. I should say that I represent rather more than such an invalid is *likely* to do, for sick people with reduced energy, especially females, are not greatly disposed toward going out when it involves much discomfort or trouble. Simply the necessity of much wrapping up always acts as a deterrent, and so do such things as cold, wind, and dust. From the 1st of September to the 1st of May I have been confined to the house by bad weather forty-two days—that is, there have been forty-two days on which I have not been able to go out even one hour, and such may fairly be reckoned as days in-doors. Of the remaining days there have been many when I could only be out from two to four hours, and when being out was a burden to the flesh. This record is satisfactory enough to me, but it shows more obstacles in the way of going out than most people anticipate from what they read and hear before coming.

I give these facts simply for what they are worth, and I am quite ready to admit that my experience may relate to an unusually bad season. I am inclined to believe, however, from talking with many old residents, that the past winter here has been about an average one—neither specially good nor specially bad. In the early part of the season there was an unbroken succession of forty-five pleasant days. Since then the weather has been variable, without long periods of either fair or foul, and the spring has been more backward and unpleasant than usual. There have been no very severe storms, and, although the mercury has been as low as 22° below zero, there has been no intense cold of long duration. While there has been a very heavy snowfall on the mountains, there has been very little in town—about fourteen inches according to my rough measurements—and there has been the usual absence of rain.

The perfect climate, of course, does not exist. All have serious objections. That of Colorado will hold its own in any fair comparison. Those who thrive in it easily overlook its defects, and are often entirely blind to them; those who do not may naturally be expected to magnify them. While it is foolish to make too much of them, as I may have done here, it is equally foolish to conceal or deny them.

The attractions of Colorado Springs, aside from its climate, strike invalids very differently, as might be expected. It is certainly an exceptionally pleasant town, and, considering its age, a remarkable one. For a permanent residence, it offers inducements which are probably not equalled in any of the other high-altitude resorts. There are handsome residences, excellent society, good roads, gas, water-works, and many other advantages. Most invalids here keep house, and find in domestic and social life all the pleasure they desire. To those coming for a brief stay in a hotel or boarding-house, the place may seem dull. If they have obtained their ideas of it from the publications of enthusiastic newspaper correspondents, railway corporations, and other interested parties, they are apt to be grievously disappointed. If they have been led to imagine a picturesque village, nestling at the base of snow-clad mountains, with pine groves, shady walks, pretty shops, and groups of in-

valids drinking healing waters from embowered springs, so much the worse for them. The mountains, the pine-trees, the springs and baths, are all several miles away, and the “shady promenades with seats to rest the stranger” exist only in the imagination. One need not expect to find here those diversions which the European resorts provide, and which lead so many of our countrymen to prefer them to our own. Hotels suitable for sick people are not plentiful in “the new West,” and he who supposes that he is going to roam comfortably over this elevated plateau from here to the city of Mexico will reckon without his host, literally. Those who expect to cure themselves speedily by “going on a ranch” will do well to investigate this form of pastoral life most thoroughly before adopting it. Lovers of fine mountain scenery can be gratified here. Colorado, like so many other sections of our great republic, is “the Switzerland of America,” and one of her recent eulogists has made things look rather blue for her rivals. “It is customary at the present time,” he says, “to speak of Colorado as the Switzerland of America. But the day is not far distant when appreciative observers will speak of Switzerland as the Colorado of Europe!” Surely nothing better than this could be desired.

Colorado can easily afford to rest on its own merits, which are indisputable, and is only injured by much of the indiscreet praise bestowed upon it by its friends. Despite all objections which may be raised, the climate is probably, as we have already said, the very best of its kind at present available for invalids, and destined to grow in popularity as its merits become more accurately understood.

COLORADO SPRINGS, May, 1884.

A SUCCESSFUL CASE OF LAPARO-HYSTERECTOMY FOR UTERINE FIBROIDS.*

By ELY VAN DE WARKER, M. D.,

SYRACUSE, N. Y.

On November 13, 1883, I was called, in connection with Dr. John Van Duyn, to examine Mrs. B., aged thirty-eight, a small brunette, married fourteen years, with one child three years old. On inspection, the abdomen was enlarged in excess somewhat of the ninth month of pregnancy, but not uniform in contour, as the umbilicus was distorted nearly three inches to the right. Fluctuation was marked, but diffuse, to the left and lower portion of the abdomen, well defined by what was evidently a cyst-wall in the upper portion, and was absent on the right side. There was general dullness on percussion except over the colon on the left side. A hypodermic needle inserted in the middle line gave us a small sample of coffee-colored fluid, which coagulated by heat and redissolved on the addition of acetic acid into a fine, flocculent precipitate. Examining through the vagina, we had difficulty in reaching the cervix uteri; owing to its high situation, it was crowded to the left and forward. A sound was with some difficulty introduced into the uterine cavity, which gave a measurement of seven inches. Its direction was obliquely to the right. Manipulation of the tumor through the abdominal walls imparted free movement to the sound. With the patient in the knee-face position, the tumor did not re-

* Read by Dr. Paul F. Mundé before the New York Obstetrical Society, March 4, 1884.

The ligature upon the uterine stump has not been removed, and has given no trouble.

The case is placed upon record for the following reasons: First. The vitality of the stump was preserved beyond the ligature by compression with the ligature just sufficient to arrest active hæmorrhage, while oozing was checked by slight contact with the actual cautery. In this way we avoided a large sloughing mass in the open abdominal wound, as is the case after the use of the *serre-nœud*, or the elastic ligature of Hegar. Second. By securing early union of the surface of the stump to the abdominal wall by careful coaptation of the peritonæum around it (Hegar), and thus closing the cavity of the abdomen. This was secured by my method, but was violated by the drainage-tube, which I regard as a mistake. Third. The free use of corrosive-sublimate solution as an antiseptic, which was employed in preparing the ligatures, dressing the stump, and in irrigating the drainage-tube and vagina.

The present condition of Mrs. B. deserves one comment. Previous to the operation she was the subject of mild mania. Before her convalescence was established she became entirely sane, and remains in that condition.

Book Notices.

A Practical Treatise on the Medical and Surgical Uses of Electricity; including Localized and General Faradization. Localized and Central Galvanization, Franklinization, Electrolysis, and Galvano-cautery. By GEORGE M. BEARD, A. M., M. D., etc., and A. D. ROCKWELL, A. M., M. D., etc. Fourth edition, revised by A. D. Rockwell, M. D., with nearly two hundred illustrations. New York: William Wood & Co., 1883. Pp. xxx-758.

Hand-book of Electro-Therapeutics. By Dr. WILHELM ERB, Professor in the University of Leipzig. Translated by L. PUTZEL, M. D., Neurologist to Randall's Island Hospital, etc. With thirty-nine woodcuts. New York: William Wood & Co., 1883. Pp. xi-366. [Wood's Library of Standard Medical Authors.]

THE two books before us are both formal didactic treatises on electro-therapeutics, and both are thoroughly practical in their aim, and thus address themselves rather to the practitioner of medicine than to the physicist or merely scientific man. Emanating, as they do, from men of long experience in the subjects of which they treat, they must command our attention; and, as representative of the latest discoveries in a field as yet imperfectly explored, they will be received with much interest by the profession.

Although in general treating of the same topics and following the same plan, the books differ somewhat in scope. Beard and Rockwell's treatise, as its name indeed implies, devotes especial attention to the physics of the subject, and goes with considerable detail into the principles of magnetism and of frictional, galvanic, and faradaic electricity. We must confess to our belief that in this regard the authors have erred in the direction of over-fullness, in that they have introduced much matter of mere historical or theoretic importance such as the practicing physician does not need to know, or, if he does, can learn much better by referring to special works on physics. More-

over, a certain obscurity of expression and looseness in the use of terms render this part of the book additionally unsatisfactory.

We refer here more particularly to the definitions and to the enunciation and explanation of the different laws of electricity. Erb, on the contrary, compresses into a few pages all the data of electro-physics that are necessary for a comprehension of electro-therapeutics, and, of necessity, in so brief a space includes nothing irrelevant.

On the other hand, in the consideration of electro-physiology and electro-diagnosis, where Erb is peculiarly full and satisfactory, Beard and Rockwell's book is meager and defective. The reaction of degeneration, for instance, which in Erb claims the greater part of two chapters, is disposed of by the American authors in a paragraph.

These shortcomings in Beard and Rockwell's treatise are, it will be perceived, due chiefly to faulty compilation and failure in properly subordinating the topics treated of. When, however, the authors no longer confine themselves to what others have done, but give the results of their own experience, much greater value attaches to their propositions, and, accordingly, the section on electro-therapeutics is by far the most satisfactory of the book. It is this that has made the latter a most valuable addition to the literature of electricity; and, as a guide in the practice of electro-therapeutics, we can cordially commend it.

When, therefore, in spite of this encomium of the American work, we assert the much superior value of the German, it will be understood that we believe the latter to possess a very great degree of merit indeed.

In fact, we can hardly imagine a book more satisfactory, for purposes both of study and of reference, than Erb's electro-therapeutics. In the combination of fullness of statement with careful condensation, in accuracy of enunciation, and in the certainty of the knowledge imparted, it leaves little to be desired.

The translation of Dr. Putzel has been faithfully executed; and, except in the matter of cuts and of typography, this edition is an excellent transcript of the original.

A Year-Book of Therapeutics for 1883. Edited by ROYAL W. AMIDON, M. D. New York: G. P. Putnam's Sons, 1884. Pp. viii-250. [Price, \$1.50.]

DR. AMIDON'S year-book of the progress in therapeutics during 1883 is a fairly complete *résumé* of the more important items contained in the journals for the year. The arrangement of topics is alphabetical—perhaps the best order on the whole in a work of this sort.

The abstracts, in general, are well made, although we have noted several mistakes which a little more care in the transcription might have remedied. For instance, the very first article—that upon acetal—contains a wrong statement of the formula of diethyl acetal and of its boiling-point, and the dose of dimethyl acetal is given as one half that of ordinary acetal, whereas the original statement is that it acts with only one half the power of acetal.

Again, on page 16, the sentence reading "It is advised as an injection in gonorrhœa" leaves us in doubt as to what is intended, while a reference to the original shows that it was hydroquinone which was recommended.

In these two cases, as in some others, the error, we should suppose, was due to relying upon intermediary sources of information—a French abstract, for instance—instead of referring to the German original.

Probably the same explanation will serve for the instances,

two of which we have noted, in which two abstracts of the same paper are given as distinct articles and under separate headings. For example, Diani's "chlorinated carboic acid" (p. 41, abstract from the "Bull. gén. de thérap.") is unquestionably the same as the "trichlorated phenol" of p. 197 (abstract from the "Lond. Med. Record"), while the more accurate designation chemically, and the one which we believe the author himself employed, is trichlorophenol.

It is not with the purpose of mere fault-finding that we point out these errors, which, after all, appear of only trifling moment. In a book of this sort we have the right to expect accuracy even in details, and a little care might have obviated all criticism.

The good points of the book are seen in its longer articles, in the selection of which much good judgment has been shown. The most important of these are the articles on chloride of barium, by Ringer and Sainsbury; Weir's article on corrosive sublimate, which will be familiar to readers of the "Journal"; Uthoff's paper on eserine; the elaborate and valuable dissertation, covering fifty pages of the book and translated especially for it, upon the physiological action of iodoform, by Rummo; Nancrede's paper on inflammation and the therapeutic value of local depletion; and the articles upon bichloride of methylene and other anesthetics and upon psoriasis. The two *revues critiques* on resorcin and on tuberculosis make us wish that the author had thrown more of his compilations into this form, since, in our opinion, there is no more satisfactory way of presenting the results of a number of papers on related subjects than by their collection in one article, where they may be compared, contrasted, and criticised.

In spite of the criticism with which we started out, and of the justice of which we feel persuaded, we believe that the book is of value, and have no hesitation in recommending it to our readers—both as intrinsically worth perusal and as furnishing a guide to sources of valuable therapeutic information.

Opera Minora: a Collection of Essays, Articles, Lectures, and Addresses, from 1866 to 1882, inclusive. By EDWARD C. SEGWIN, M.D., Clinical Professor of Diseases of the Mind and Nervous System in the College of Physicians and Surgeons, New York, etc. New York: G. P. Putnam's Sons, 1884. Pp. x-687. [Price, \$5.]

As is mentioned in the title, this volume contains nothing but what has already appeared in print, and hence has been subjected to criticism. When we consider the magnitude of medical literature, and of the literature of diseases of the nervous system in particular, we must confess that the publication of a volume of miscellaneous essays is somewhat venturesome, unless intended for private distribution, as Dr. Seguin tells us the original intent was in this case. Emanating from a writer of the scholarship and acumen of Dr. Seguin, however, such a publication comes rather in answer to a requirement than otherwise, and we feel certain that his friends and the pupils who have listened to his lectures—models of clearness—at the College of Physicians and Surgeons for the past few years, will be glad that the original intention was changed and the edition made sufficiently large to admit of its being put upon sale. As has been said, professional criticism has already established the scientific status of the contents of the book, and that will remain. As a literary production it must also take a high rank, and we hazard the assertion that there are few books in English or American medical literature with so pure, readable, and intelligible use of our language as will be found in this. Dr. Seguin has been fortunate in the choice of an editor in Dr.

Amidon, and, as the author courteously acknowledges in his preface, certain important and meritorious features of the book are due to Dr. Amidon.

A Manual of Obstetrics. By A. F. A. KING, M.D., Professor of Obstetrics and Diseases of Women and Children in the Medical Department of the Columbian University, Washington, D. C., and in the University of Vermont, etc. With fifty-nine illustrations. Second edition. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. xx-25 to 338, inclusive.

WE are glad to observe the token which this second edition gives that Dr. King's work has been properly appreciated by the profession. The author's plan in its preparation was not an ambitious one; he has contented himself with giving an abstract of the current teaching in obstetrics, but he has done it so well, has brought it so within the comprehension of the general reader, and has so infused into it the unmistakable marks of his personality, as to make it a hand-book of unusual excellence.

BOOKS AND PAMPHLETS RECEIVED

A Treatise on Chemistry. By H. E. Roscoe, F. R. S., and C. Schorlemmer, F. R. S., Professors of Chemistry in the Victoria University, Owens College, Manchester. Vol. III. The Chemistry of the Hydrocarbons and their Derivatives: or Organic Chemistry. Part II. New York: D. Appleton & Co., 1884. Pp. ix-655. [Price, \$5.]

Diseases of the Heart and Thoracic Aorta. By Byrom Bramwell, M.D., F. R. C. P. E., Lecturer on the Principles and Practice of Medicine, and on Practical Medicine and Medical Diagnosis, in the Extra-academical School of Medicine, Edinburgh, etc. With 317 illustrations. Edinburgh: Young J. Pentland, 1884. Pp. xvi-788.

The same. New York: D. Appleton & Co., 1884. [Price, cloth, \$8.]

Lal. A Novel. By William A. Hammond. New York: D. Appleton & Co., 1884. Pp. 466.

Notes on Operations on the Eye. By Ram Kishen, L. M. S., Lahore, Assistant Surgeon. Lahore: "Tribune" Press, 1884. Pp. 2-ii-78-iii.

Del Bacilo de Koch en la Tuberculosis. Importancia del Examen Microscópico de los Esputos en el Diagnóstico de la misma, y Técnica Especial para la Investigación de dicho Parásito. Por el Dr. Leopoldo Lopez García, Director, Propietario y Profesor Libre de un Laboratorio de Histología, etc. Madrid: Establecimiento Tipográfico del Hospicio, 1884. [Price, 75 céntimos.]

Correspondence.

LETTER FROM VIENNA.

Abdominal Surgery.—Porro's and Freund's Operations.—Deaths in the Faculty.—Female Students.

VIENNA, July 10, 1884.

THE summer semester closes on the 15th, though it had practically come to an end on the 1st of the month, when several of the principal lecturers ceased their attendance.

However, the surgical and gynecological clinics are still in full blast, and the past week has witnessed several interesting operations, among which was a Porro by Spaeth, an œsophagotomy by Billroth, the removal of an echinococcus-cyst of the liver by Albert, and several laparotomies. Though some of the capital operations here are to be classed rather among the curiosities of surgery as regards their practical value, there is a certain dash and boldness in their conception and execution which can not fail to impress one who has been accustomed to our more conservative ideas.

At the same time it must be confessed that the results are

often so gratifying as to apparently justify the most heroic methods of treatment.

There have been only two cases of Porro's operation in Vienna during the past year (against four the previous year), the second of which I was fortunate enough to witness a few days since. The patient, a multipara, was a dwarf with a pelvis of 4-4½ ctm. in the conjugate. The operation was performed with such rapidity that in less than five minutes the child was crying in the nurse's arms, while the hæmorrhage (which was very severe, as the placenta was attached to the anterior wall, and hence was divided in the uterine incision) was completely controlled with a coil of rubber tubing. The patient succumbed to peritonitis on the sixth day, a termination which has happened in four out of the last six cases.

Professor Carl Braun has performed not fewer than ten laparo-hysterotomies for fibroid tumors during the present semester, only one of which has resulted fatally. When we remember the formidable nature of these operations, and the facts (which I emphasized in a former letter) that they are performed in a crowded lecture-room and that the assistants are in constant contact with the cadaver, the statistics will appear surprising. They certainly show what a scrupulous attention to cleanliness, without the use of the spray, can accomplish.

A Freund's operation was attempted (but not completed) at the same clinic this week. Having now witnessed four of these terrible affairs, all of which terminated disastrously, I am not prepossessed in favor of an attempt to add a few months to a woman's life against such desperate odds. I mentioned the fact that Billroth had recently performed an œsophagotomy for stricture. The entire proceeding occupied about four minutes, and was perfectly successful.

Three members of the medical faculty have been removed by death during the past ten days—Professor Arlt, and Dr. Kolisko and Dr. Massari. The latter, as is doubtless known to most of your readers, was the son-in-law of Professor Carl Braun, and has occupied the post of Docent in gynecology during the past six years. He was soon to become a professor. Arlt had just succeeded to the position formerly occupied by Stellwag. He was in his sixty-eighth year, and hence would shortly have been retired.

Reports of the cholera do not trouble us much, but I have noticed that there is a sharp eye kept on all hospital patients with suspicious symptoms. The weather is excessively hot, but the sanitary condition of the city seems to be very fair; that is saying a good deal.

There is not much gossip to retail at present. Just now there are rather fewer Americans in Vienna than usual; perhaps it is a little early for the summer gleaning to begin, after the departure of the army of students. A goodly number of our countrymen are not men at all, for a little colony of fair M. D.'s has been established in the hospital, and is quietly and yet pluckily solving the problem of co-education. In justice to our professional sisters I would say that, however opinions may differ as to the advisability of their breathing the Vienna atmosphere, those who have made the experiment deserve in the main only credit for their combined modesty and firmness. The "strong-minded" element is wanting, and the ladies whom I have met have received such polite attention as we do not generally credit to Germans. It forms a very interesting break in the daily "struggle for supremacy" at lectures to see our fair friend standing up for her rights and claiming her own little share. Perhaps her influence will yet act as a soothing syrup to the untutored Russian. That were devoutly to be wished! At any rate, the doubt as to whether a modest woman can study medicine side by side with those of the other sex has been dispelled by the plucky little American ladies.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & Co.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, AUGUST 2, 1884.

THE INFECTIOUS CONVALESCENT.

SEVERAL weeks ago we published the substance of a circular addressed by the secretary of the State Board of Health of New York to a number of persons who, either from their knowledge of medicine or from their experience with schools, were assumed to be capable of throwing light on a question with which the board justly felt itself called upon to deal—the question, namely, as to the length of time that ought to elapse after a patient, especially a pupil at a school, was so far convalescent from an infectious disease as to be able to go about before it became safe for persons susceptible to the infection of the disease to come in contact with him, the matter of fomites being left out of account. At the time we stated our appreciation of the importance of the inquiry, and expressed our hope that the question would meet with adequate discussion by medical men. While we still trust that the circulars sent out by the secretary have in many instances led those to whom they were addressed to furnish the board with data bearing upon the matter, we regret to say that, so far as we have been able to ascertain, the subject has not met with consideration by the profession in any other form. When we reflect that the essential question is one of those with which practicing physicians have to deal almost daily, and that they must, therefore, have formed some ideas and accumulated some facts tending to its solution, the unbroken silence that has been maintained is somewhat remarkable, not to say discreditable. Now that the matter has been broached, however, we are satisfied that it will not be allowed to fall flat, but will be made the subject of discussion by our medical societies and by individual physicians.

A cognate matter, we are pleased to observe, is meeting with attention of a very practical sort, although not in this community. We refer to a movement recently set on foot in London for providing proper retreats for infectious convalescents, where their comfort and the demands of their health will be duly attended to without subjecting them to the enormous expenditure of money which, as things are managed now, seems to be the only alternative for the convalescent who is sufficiently conscientious to pay some regard to the safety of his fellow-men while seeking change of air for himself. This degree of unselfishness is seldom met with, it is true, but perhaps this is scarcely to be wondered at, considering the many circumstances that tend to nip it in the bud, and there is no knowing to what extent it might be developed with a little assistance. That there is great need of such aid to well-meaning persons, as well as of a certain compulsion in the case of those who ignore the rights of society, is most vividly set forth in a recent number of the "Pall Mall Gazette" by Mr. H. C. Burdett, with whose in-

terest in the subject of hospitals and their management many of our readers are acquainted. Mr. Burdett states that he lately found himself "boxed up" in a railway carriage with a man convalescing from small-pox, with no possibility of escape for an hour, for it was on an express train, which was not to stop for the first fifty miles. The convalescent was on his way to a fashionable seaside resort, where he had engaged lodgings. In another instance, lodgings were relet to the mother of a large family at the very time when one of the rooms was occupied by the body of a person who had died of small-pox. In still another case, some well-to-do people, heedless of their physician's remonstrances, took their children, who were then convalescent from scarlet fever, to a popular watering place; and, not content with infecting the railway carriage and one set of apartments, changed the latter for various reasons three times within ten days, and so left the seeds of disease in three houses at least. Mr. Burdett aptly compares a convalescent under such circumstances to a pepper-box filled with infection and shaken over the heads of the community.

As a means of breaking up this wholesale sowing of infection, the Home Hospitals Association, of London, was to hold a meeting on the tenth of June, for the purpose of taking steps toward the establishment of a Convalescent Home Hospital. The plan contemplates the reception of all persons recovering from sickness, as at a hotel, but with this essential difference, that ample provision is to be made against any inmate being a source of danger to the others. There will be a resident medical superintendent, a corps of skilled nurses, and special cooking arrangements. On the one hand, the noise, the publicity, and the bustle of a hotel will be avoided, and, on the other hand, the damp sheets, the slipshod attendance, and the general discomfort of ordinary lodgings. Arrangements will be made for conveying convalescents from their own homes to the seaside, a proper ambulance taking them to and from the railway station, and their isolation being secured during the journey by rail, after which the railway car will be disinfected. It will readily be understood that such a work as this is by no means easy of accomplishment, but we look forward to the execution of the London plan with an interest not devoid of confidence in the result, for the undertaking is in good hands. In the event of its success, it can not be long before our own people will be inclined to follow the example.

A VIVISECTIONIST'S PURGATION.

FROM a certain piece of property in the French village of Colombes the howls of about forty dogs and the screeches of more than that number of cats are borne to the unwilling ears of the neighboring residents. These animals are described as by no means the choicest of their respective kinds, and it is alleged against them that, besides their unmelodious cries, they give forth odors which make the quarter decidedly unpleasant. There are those, indeed, who aver that the premises on which the animals are kept constitute practically a sort of lazaretto, and that the effluvia arising therefrom are a source of danger to their health. On this account the occupant of the property has

been proceeded against in the courts, and, as we learn from the "Progrès médical," has been condemned to pay a fine of five francs. The person thus mulcted is an old lady who makes it her business to gather in all the stray dogs and cats that she meets with on the streets.

This lady is no less a person than the widow of the great physiologist, the late M. Claude Bernard, and her eccentric behavior is accounted for in this wise: M. Bernard, as is well known, practiced vivisection, but early in the course of his married life his wife became a violent opponent of the practice, and their disagreement in the matter is understood to have made their life anything but a happy one, and finally to have brought about their separation. M. Bernard having at length died, his relict's old tenderness has risen from its ashes, and, as the story is told, she has gone to work systematically to expiate his offenses against the lower animals by showing kindness to as many stray dogs and cats as opportunity may allow; her idea being that, when at length she has succored as many distressed brutes as he was the means of slaying, his purgation will have been accomplished vicariously, and her soul and that of her late husband will be ready to meet in Paradise. How unfeeling it is of the people of Colombes to interfere with the prosecution of this scheme!

MINOR PARAGRAPHS.

A MEDICAL NOVELIST.

THAT a member of the medical profession should have chosen to write fiction is nothing specially new, in view of the literary achievements of Goldsmith, Smollett, and a number of others who might be mentioned, but at first sight it seems somewhat remarkable that so busy a man as Dr. William A. Hammond should have followed this course. The wonder diminishes, however, when we cast a look back at his articles published twelve or fifteen years ago, in a psychological journal of which he was the editor, which, though nominally medical, were really quite indicative of his *penchant* for romance, and gave abundant evidence that, if he ever did actually take up with literature as an occupation, he would make a creditable show. That he has done so, in the novel called "Lal," recently published, can not be questioned, we think. The construction of the story is artistic, and the style in which it is told is vigorous and clear. Here and there we catch a glimpse of the medical element in the author's training, but never of anything like a strained attempt to make a show of medical learning. Having avoided that rock in his first venture, the author may in future give further play to the romantic vein which runs through the observation of a medical man, and yet not bring up against it, if, as we understand his purpose to be, he writes more works of fiction.

NEWS ITEMS, ETC.

The Cholera in Europe.—During the week the outbreak in France seems to have abated decidedly in virulence, but the territory affected has been enlarged, and the disease has crept into Italy. Thus far, the fatality has not been very great, and it is to be hoped that the worst has been seen of the visitation, but it should be borne in mind that great epidemics have sometimes begun with no more virulence, and that intervals of comparative quiescence have been known to be followed by terrible recrudescences. It may be, as the Health Officer of the port of New York is reported to have suggested, that the decline in the

number of victims in Toulon and Marseilles is to be imputed rather to a falling off in the "raw material" than to any decrease in the actual virulence of the disease. Certainly the state of the poor people left in those cities is sufficiently appalling, but, unaccountable as the doings of a panic-stricken population are apt to be, it is difficult to realize that the reports can be true to the effect that hostility is shown toward the physicians, so that, as it is said, it is dangerous for them to go about the streets after nightfall. During the week a death supposed to have been due to cholera took place on a Mississippi River steamboat, the victim being a child belonging to a family from Mexico, and the Surgeon-General of the Marine-Hospital Service at once took prompt and most appropriate measures to prevent the spread of infection; but it soon became reasonably certain that the disease of which the child died was not cholera, but the ordinary inflammatory diarrhoea of infants.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 29, 1884:

DISEASES.	Week ending July 22.		Week ending July 29.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	3	1	0	0
Typhoid Fever	20	6	21	9
Scarlet Fever	51	16	50	9
Cerebro-spinal meningitis ..	4	4	5	5
Measles	164	31	129	27
Diphtheria	27	17	31	19
Small-pox	1	0	0	0

Yellow Fever is reported as still rife on the Isthmus of Panama, and to be spreading rapidly in the State of Sonora, in Mexico. In consequence of the latter information, the Surgeon-General of the Marine-Hospital Service has instructed our quarantine official at Nogales to exercise the utmost vigilance. The sanitary officers of New Orleans have authorized a formal statement to the effect that a post-mortem examination in the case of death recently attributed to the disease in that city has failed to support the assumption that the case was one of yellow fever.

Small-pox.—Several cases are reported to have come to light in Hoboken, N. J., since last Sunday, and Tuesday night a fishing smack anchored off Stapleton, Staten Island, from which a man went ashore and was discovered to be suffering with the disease. As the vessel was not within the jurisdiction of the Health Officer of the port of New York, the local sanitary officers were obliged to take charge of the man. No new cases have been reported in this city, notwithstanding the exposure that must have happened to many persons by reason of the travels of a man sick with the disease, as was related in our issue for week before last.

Actinomycosis.—A case of this disease in the human subject is said to be under observation in the Cook County Hospital, in Chicago.

The late Dr. Ambler.—A brass tablet has been prepared, to be placed in the village church at Culpepper, Va., bearing the following inscription:

JAMES MARKHAM AMBLER,

PASSED ASSISTANT SURGEON, U. S. NAVY,

Died on the banks of the Lena River during the memorable retreat of the ship's company of the U. S. Arctic steamer Jeannette, in the year

— 1881.

His sense of duty was stronger than his love of life.

In memory of his noble example and heroic death this tablet is erected by the medical officers of the United States Navy.

The "Weekly Medical Review" announces that, after the first of January, it will be enlarged, and that a special department of obstetrics and gynecology will be added, under the editorial management of Dr. G. J. Engelmann, of St. Louis. It will then be known as "The Weekly Medical Review and Journal of Obstetrics and Diseases of Women." The special department will be paged separately, so that it can be bound by itself. We congratulate the "Review" on having secured Dr. Engelmann's services, and trust that the success of its proposed plan will be complete.

The National Board of Health held a meeting in Washington on Wednesday, July 30th, at which officers were elected as follows: President, Dr. James L. Cabell, of Virginia; vice-president, Dr. Stephen Smith, of New York; secretary, Colonel George E. Waring, of Rhode Island.

Recent Paris Theses.—According to the "Progrès médical," the following theses have recently been read: July 16th: The Points for Auscultation in Obstetrics, by M. Cantacuzène; Version in Contracted Pelvis, by M. Grisel; The Poison Apparatus of the "Vive" Species of Fish, by M. Gressin; The Vaso-Motor Nerves, by M. Karline; Arabian Medicine in Algeria, by M. Ben Larbey; The Treatment of Cold Abscesses by the Injection of Iodoformized Ether, by M. Mattei; Syphilitic Phthisis in the Adult, by M. G. Jacquin. July 17th: Congenital Ascites, by M. Poirier de Narçay; Rheumatism during Pregnancy, by M. Alexandre; Osseous Lesions in Convalescence from Typhoid Fever, by M. Gelez; Influenza, by M. Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 20, 1884, to July 26, 1884:*

WRIGHT, J. P., Major and Surgeon. Granted leave of absence for one month, on surgeon's certificate of disability. Par. 3, S. O. 89, Headquarters Department of Texas, July 17, 1884.

HARTSUFF, ALBERT, Major and Surgeon. Leave of absence extended one month. S. O. 79, Headquarters Division of the Missouri, July 18, 1884.

REED, WALTER, Captain and Assistant Surgeon. Relieved from duty at Fort Sidney, Nebraska, and ordered for duty as Post Surgeon, Fort Robinson, Nebraska, relieving Assistant Surgeon Henry McElderry, U. S. A. Par. 2, S. O. 62, Headquarters Department of the Platte, July 23, 1884.

BENHAM, R. B., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Brown, Texas. Par. 1, S. O. 90, Headquarters Department of Texas, July 19, 1884.

STRONG, NORTON, First Lieutenant and Assistant Surgeon. Granted leave of absence for two months, to take effect when relieved from duty in Department of the Platte. Par. 2, S. O. 68, Headquarters Division of the Missouri, June 27, 1884.

Society Meetings for the Coming Week:

MONDAY, August 4th: Chicago Medical Society (The Etiology, Pathology, and Treatment of Cholera, by Dr. J. H. ETHER-

IDGE; Cutaneous Therapeutics, by Dr. P. C. JENSEN; Some Remarks on Aneurysms, with a recent specimen, by Dr. J. A. ROBISON).

TUESDAY, August 5th: Elmira, N. Y., Academy of Medicine; Ogdensburg, N. Y., Medical Association; Medical Society of the County of Hudson, N. J.

WEDNESDAY, August 6th: Medical Society of the County of Richmond, N. Y.

OBITUARY NOTES.

Dr. George S. Burton, of East Greenwich, R. I.—Dr. Burton, best known as Surgeon Burton, of the Third Rhode Island Heavy Artillery, during the late war, died of consumption in East Greenwich, July 21st, in his fifty-first year. He was well known for his medical services and his personal bravery in the campaigns in South Carolina. After the war he began practice in Charleston, S. C., but the state of his health compelled him to go back to Rhode Island, and, so long as his health allowed of it, he continued to practice in East Greenwich. Dr. Burton was highly beloved and respected, both for his professional ability and for his character as a man and a scholar.

Dr. Dwight Ruggles, of this city, a graduate of the Philadelphia Medical College, in the class of 1849, died very suddenly on Friday, July 18th.

Proceedings of Societies

BUFFALO MEDICAL AND SURGICAL ASSOCIATION.

Adjourned Meeting of July 15, 1884.

The President, Dr. F. W. BARTLETT, in the chair.

The Status of the Midwife in Buffalo.—This was the title of a paper in which Dr. J. H. PRYOR presented certain facts concerning an abuse that had existed in Buffalo for years, and one which was constantly increasing. The nature of its cause, the magnitude of its influence, and the questionable character of its results made it a question of intrinsic interest to the profession—he referred to midwifery as practiced by the midwife. In certain districts of the city, where most of the inhabitants were recently arrived immigrants and foreign-born citizens who clung persistently to their native traditions and modes of life, many customs of a primitive type prevailed. The one outgrowth which interested us, because so closely allied to medicine, was the midwife. She was a woman of their class, and represented the level of their intelligence. The people among whom she sought employment summoned her because they had been accustomed to her assistance in other countries, where the scarcity of physicians made her desirable, if not obligatory; because the midwife performed a dual function and offered to act as *accoucheuse* and nurse for a moderate fee, generally three dollars or five dollars, which her patient could afford to pay; because they believed that the midwife was a safe attendant in ordinary cases, and could call a physician if the labor became complicated or tedious. The desire to economize, and the aversion to masculine help, which was sedulously encouraged by the midwife, had something to do with this selection. Even the superficial observer could detect the cause of this defective reasoning, as it appeared upon the surface. It was plainly ignorance. If these people were not generally ignorant, they showed deficient intelligence in this particular instance. It seemed fair to state that

no woman would willfully risk her life and that of her child in the hands of a blundering and ignorant person if she was acquainted with the dangers which surrounded the event of childbirth and appreciated the difference between such assistance and that which the skilled physician could offer. He adduced, as proof of this statement, that the business of the midwife was limited to sections of the city where ignorance most abounded. The numbers of the poor and ignorant increased rapidly, and the midwives multiplied accordingly. The certificates at the City Hall showed that there were over one hundred at work in Buffalo at the present time, and that last year about *two thirds* of the cases of childbirth were reported by them.

These facts stimulated an inquiry into their origin, the mode of their education, their qualifications, and their results to humanity. In the cities of Europe the midwife must possess a certificate of varying value, to show that she was qualified, before she was allowed to undertake her duties in the lying-in chamber. Here she had ever flourished without restraint or opposition. The many phases of progress had left her untouched and unmodified. She acquired her title by squatter sovereignty, and fixed her debt to society according to her own statute of limitations. To-day she originated, as she did in the barbarous ages, by the cry for assistance, and, like each new journal, supplied a long-felt want. A woman might be called to act in emergencies, and, continuing, make midwifery a vocation. The great proportion, however, accepted midwifery as the least laborious and most remunerative employment by which to earn a livelihood. This accounted for the large number of widows who acted as midwives. In either case, what were her recommendations? What had been her preliminary preparation? Her intellect was slight and untrained. Her education was meager. Placed in competition with enlightened people, the invariable law of fitness would oblige her to resort to physical labor as her proper place in the economy of the world. There was absolutely no other position demanding mental ability which she could fill. Yet she attempted to perform a work which only the well-equipped and broadest mind could master. He would not go deeply into her incapacity; it was too apparent. Unconscious of her ignorant condition, she would not correct it. As no plan of education had ever been enforced in this country, the midwife followed a wayward course, and was compelled to accept the limited knowledge she might think required and what experience would bring her. Her means of learning were therefore narrowed and confined to two sources. Many books upon midwifery, abridged, of course, had been written, and she could obtain them if she knew of their existence and desired them. Could she read them intelligently? Judging from the appearance of the certificates on file in the city, many of their number could not read or write correctly. Again, no woman of her mental caliber could study a book on midwifery, properly and understandingly, without any knowledge of the primary branches of medicine.

We now came to the only way left them to gain any knowledge which could be at all reliable—viz., experience. She entered the lying-in room to begin her training. What sad havoc must ensue as she went blundering on to the unsated time when she at last became what some considered a fairly trained midwife! The mothers who died and the children still-born could not be estimated, because they were recorded over physicians' signatures. The reader purposely avoided giving instances of reckless management which had come to his notice. Every physician had met with the different forms of suffering and despair which sprang from the lamentable ignorance of the midwife, who had been called by an English writer the Herod of society. Occasionally there was one who, appreciating her grave duty to womankind, consulted with physicians in times of doubt, and

improved by the contact. This added another way of advancement, which was commendable, but not apt to be over-indulged in. But inefficiency was her birth-mark. A defective training modified the material but slightly, and left her incompetent, as it found her unfitted. Let us fix the compass of her acquirements at a time when she was supposed to have arrived at a point which permitted of judgment. The truths which the midwife might gather were isolated, and no discrimination grouped them into a system from which precise data could be drawn. Yet her advance showed the reflection of many impressions which had left a changing influence, and been productive of a state of accomplishment colossal in its range of effort, but strikingly simple in its display of learning. There was a discrepancy between her pretensions and her actual worth. Perhaps, in a certain proportion of cases, the midwife, acting under the doctor's direction, would not be a dangerous attendant, because many labors needed no management beyond her capability. An attendance upon a case of pregnancy should begin before labor occurred. Many questions of nicety relating to hygiene and prevention called for superior judgment. Certain conditions might be present which, if not perceived and corrected, had a grave effect upon the mother and child, and so complicated the case as to carry it beyond relief. He would only mention deformities and diseases such as albuminuria, to illustrate his meaning. When a labor became protracted or tedious, the midwife used none of those instruments of precision which were such potent allies of the physician in assisting nature's intent. Why the forceps had never got into the midwife's satchel, along with her preparations of opium, chloral, and ergot, he did not know. Evidently not from fear of the law; else, why did she employ poisonous drugs, of the power and action of which she knew nothing, without interference? The patient of the midwife was denied that boon to womankind, the forceps, unless the physician was sought for to apply it. The indications and time for its use were left to the midwife's discretion, and the physician might rest assured that he would not be called until all her efforts had failed and every hope of success by other means had vanished. In the mean time the pressure of the child's head upon the adjacent parts might cause those distressing injuries which would afterward require operative procedure. The third stage of labor ushered in the time of greatest peril to the mother. She incurred the danger of puerperal hæmorrhage and convulsions, retained placenta, hour-glass contraction, etc., which only skill and varied resources could meet. The midwife frequently became the cause of such accidents through improper management, and was unable to rectify her blunder or the consequent condition. It was during this stage, also, that septic infection was strictly to be guarded against and the avenues of contagion carefully sentinelled. Of all the lamentable blunders which the midwife committed with her patient, her non-observance of the law of cleanliness was the most censurable. Imposing upon herself two senseless rules, to which she closely adhered, she changed the patient's clothing, bedding, etc., as little as possible, and she never made use of water unless it was absolutely necessary. True, some employed vaginal douches, but for this purpose they used a syringe which, like their catheter, was usually dirty, and had done long and continuous service in many cases. He recalled a case of negligence and ignorance on the part of a popular midwife who was administering douches to ten women daily. One had puerperal fever, nine had not. She used the same syringe for all, and did not change her clothing, nor did she perform any ablution to prevent contagion. The final result upon the nine healthy women he had never learned, but the case was significant.

Compare this novice with the physician. Each practiced

obstetrics. One brought intelligence, trained perceptive faculties, a careful education, and complete aid to the task; the other's credentials were ignorance, misdirected and untaught observation, deficient education, and glaring incompetency. One was equipped with accurate knowledge of one of the most scientific departments of medicine, almost mathematical in its exactness. The other depended upon a blind experience gained by her mistakes, from which she collected a chaos of facts which were uncertain in their application. The comparison revealed quite a wide difference in proficiency. He regretted to say that he could not furnish statistics to show the difference in results. The board of health of the city did not consider a midwife's certificate of still-birth valid, and it must be reported by a physician. Thus, no estimate can be made.

In the absence of any at home, he would cite some collected by Merryman in England. From 1657 to 1681, inclusive, a period of twenty-five years, when cases of childbirth were almost entirely in the hands of the midwife, there were 273,763 christenings and 14,397 abortions and still-born children. So that the children born dead were to those born alive as one to nineteen. During the twenty-five years from 1791 to 1815 the practice of midwifery was more generally conducted by men, and the number of christenings was 492,464, and the still-born children were 15,084, making a proportion of one to thirty—a diminution of more than one third. In the first twenty-five years there were 288,160 parturitions. Of the mothers, 6,686 died in childbirth; in the proportion of one to forty-three. In the second series there were 548,448 labors, and the number of deaths in childbirth were recorded as 4,684, or in the proportion of one to one hundred and eight. To no other cause could this diminution of mortality in childbirth be attributed than the more judicious management of women during and after labor.

To practice a specialty in medicine, one must have a diploma and be adjudged qualified in the various branches connected therewith. Blot out the tradition and customs of the past place the question in its true light, and what unwritten and mysterious law granted the midwife the privilege of practicing obstetrics, when, if she attempted ophthalmology, laryngology or any other special branch, a hue and cry would rouse the law to place her either in jail or in a lunatic asylum? The hope of a future competent midwife was delusive. She could never exist until she became a physician. That step would carry her into a different sphere and her past identity would be lost.

For the purpose of grouping the salient facts in a condensed form, he would resolve them into a series of propositions:

1. The midwife owed her origin and introduction into this country to ignorance, and she was fostered by a false custom engendered elsewhere. Her business was confined to localities where these were rife, and nowhere else was the demand manifest.
2. The need was supplied by women of a low grade of intelligence who were in every way unfit to undertake such a vocation.
3. Her incapacity, combined with the slight opportunity for improvement offered her, limited her means of education almost entirely to blind experience.
4. This method of self-instruction caused the women under her care much needless suffering and distress without any compensatory good.
5. For sufficient reasons—viz., mental inability, incomplete education, and never-ending probation—she never reached a period where she could be called at all proficient in her art.
6. Her qualifications for practicing a branch in medicine were best revealed by comparing her attainments with those of the physician.
7. This test proved her thorough incompetency and sug-

gested the only manner by which her condition could be changed or improved.

8. Nothing but determined interference could accomplish this aim, and, until it was attempted, she remained a dangerous factor in civilization.

During the last year a disposition to correct this abuse had been manifested in this State. Recently a method had been advised which resembled that adopted in Europe. A bill providing for the establishment of a college of midwifery, to educate and grant diplomas to these women, had been presented to the Legislature, but had not become a law. The only plea in favor of such a bill was that it might, after a lapse of time, elevate the standard by rejecting the very ignorant and supplying better facilities for attaining proficiency. The points of objection were numerous. It would be very difficult to crowd these women into such a college. Again, the conditions in this State were not similar to those in foreign countries. Elsewhere the midwife might be necessary; here she is not, and this method would only continue to increase the number. The reader had been informed by Dr. H. J. Garrigues that, according to the last census, there was one physician for every two hundred and seventy-eight females in this State. Now, take from that number the girls under puberty, the women who had passed the menopause, the unmarried and the widowed, and those who did not bear children, and did it not seem probable that, if each physician was slightly energetic, he could attend to his quota? If it was found that he could not, more could be educated at the medical colleges, which are plentiful in this State. These principal objections showed the fallacy of such a course. In the States of Illinois, West Virginia, Missouri, and Minnesota the midwife was treated in a different manner—very conservative in its motive and effect. She was compelled to pass an examination, how rigid he did not know, but probably insufficient in its scope. If she passed successfully, the law obliged her to register and obtain a license. It did not recognize a diploma issued by a college of midwifery. The chief argument against this plan of procedure was that its efficacy was limited, and that it did not meet the question on a proper plane. The arbitrary conclusion arrived at by a consideration of the midwife's status made the final settlement of this question center in her being abolished. This might be accomplished in two ways: by a lingering conservative policy, which gradually led up to the ultimate act, or by the power of the law. The law of 1880, which annihilated quacks, had never tested the midwife's legality, so far as he knew. Yet, if that law was rigidly enforced, no court of justice could acquit her. Its reading announced her guilt. The means, then, lay in testing this law as it was framed, or in petitioning the Legislature for one which was so perfectly adjusted to her case that she could not escape.

Dr. ROCHESTER said he had seen a great many atrocities committed by midwives. They did not use water, but made the patient wallow in her dirty clothes for a week. They undoubtedly carried diseases from one bedside to another. It was very much worse here than in Europe, where education was required. It was, however, impossible to convince some women that a man was better than a midwife, and there was the additional inducement of cheapness of attendance. He thought the poor should be attended by physicians at a moderate compensation, or some provision made for an obstetrical dispensary service.

Dr. COAKLEY mentioned the abuse of alcohol by midwives. They administered spirits in almost every case, without regard to the condition of the patient. He remembered a woman in a southern city, who had the largest obstetric practice in the place, charging ten dollars a case, and who had attained to considerable skill and dexterity in the treatment of certain puerperal disorders.

Dr. HARTWIG thought it as much a political as a medical question. This was a free country, and, if a patient desired help, let her seek it where she would. They were also discussing the midwife in Germany at this time, although she was there educated to a high degree. She was especially taught to diagnosticate positions, and was required to call the physician when needed. The foreigners here in America knew very well how to distinguish the educated midwife of Germany from the self-made one. The real danger was in her freedom. He mentioned a midwife of Buffalo who had told him she had had one thousand successive successful cases, among which she had turned fifty times in cross presentations, had had fifty footling cases, and one of placenta prævia, had three times called a doctor to apply the forceps, and had fifty times removed the placenta with her hand. No mother or child had died during confinement. He believed she told the truth. There was place for the midwife in this country. She washed the child, prepared food for the mother, and did many things the doctor could not do. Labor was really a physiological process, and a midwife was just the person to oversee it.

Dr. WEIL stated that the physicians already charged sufficiently small fees, the old ones especially, and mentioned instances.

Dr. RING thought every woman entitled to treatment by physicians, because she is a woman and a mother. We owed it to her to abolish the midwives.

Dr. STOCKTON had formerly been of the same opinion as the essayist, but he did not now consider midwives dangerous. He spoke of a midwife who had had one thousand cases without a death, and other physicians had told him of just such cases. The work, in his judgment, belonged to the midwife.

Dr. HOPKINS was amazed to learn that all the physicians of this city together had charge of but one third of the obstetrical cases. He could not believe that the average midwife could have a thousand successive cases without the death of a mother. Certainly, no physician could boast of such results. He thought one evening not sufficient to consider this matter, and the society should take time to study it. We ought to address a memorial to the State Medical Society upon this subject, and learn if in other parts of New York the profession attended at but one third of the births.

Dr. VAN PEYMA thought the paper one-sided, although it showed the necessity for reform. Having much to do with midwives in his practice, he had come to respect them highly, especially those with foreign diplomas. In his own family he would certainly prefer a midwife to a district physician. The statements of midwives were not reliable, as they called doctors in bad cases, and the death certificates were signed by them. The midwife to whom Dr. Hartwig referred was not trustworthy. The one to whom Dr. Pryor called attention in his paper he considered one of the best at East Buffalo.

Dr. CROXY believed midwives to be very useful. He had noticed that they were all widows. Perhaps their own experience had led them to adopt this calling. He mentioned one who had attended five thousand cases in twenty-five years. She was very ignorant. He asked her where she had acquired her art. She answered that she had read six books. Being asked the name of the author, she responded, "My husband." He thought midwives should be admitted to lectures upon this subject at medical colleges. Many of them were cleanly, and many were not. Some were acquainted with antiseptics.

Dr. MANN felt that it would be better to dispense with the midwives and make use of physicians only, but it was not practicable. As we must have them, it was the duty of the profession to try to educate them.

The PRESIDENT recalled several instances of maltreatment of

puerperal women by midwives. The statistics given by Dr. Hartwig's midwife were, in his opinion, utterly unreliable. The midwives used ergot too much and indiscriminately. Many women were afraid of a doctor because of his instruments.

Dr. PRYOR, in closing, stated that in his paper he had spoken only of the average midwife, referring to the one hundred of the city as a class. He thought the gentlemen who had spoken had in mind only the one or two with whom they had severally been brought in contact. He had purposely avoided citing instances, although he had innumerable such to offer, because he wished to treat midwives as a class. If Dr. Van Peyma considered the one midwife he mentioned as one of the best in Buffalo, that was a good criterion from which to judge of the rest.

Dr. HOPKINS, Dr. RING, Dr. HARTWIG, Dr. PRYOR, and Dr. VAN PEYMA were appointed a committee to give the subject further consideration and report at a subsequent meeting.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twentieth Annual Session, held at the Grand Hotel, Catskill Mountains, N. Y., Wednesday and Thursday, July 16 and 17, 1884.

Wednesday's Proceedings.—Evening Session.

(Concluded from p. 104.)

Embolism of the Central Artery of the Retina.—

Dr. H. S. SCHELL, of Philadelphia, read a paper in which he related the case of a woman, aged seventy-one years, who while walking saw different colors before the left eye. This was followed by sudden loss of vision. The left pupil was dilated, and there was some drooping of the upper lid. Examination of the heart showed insufficiency of the mitral valve and hypertrophy of the left ventricle. The ophthalmoscope showed swelling of the disc, and edema of the central portion of the retina. There was no red spot at the macula. The veins were smaller than the arteries, which were about of the normal size. In the inferior arterial branch there was an apparently empty space. Pressure on the eyeball emptied the veins completely, but had no effect on the arteries, yet, after massage had been practiced for some minutes, a regular current was induced, but this blood-current was broken into little cylinders. The patient stated that before the attack the left eye had been the better of the two. The right eye presented a somewhat ill-defined and muddy disc, and the visual field was somewhat contracted. Iodide of potassium, in five-grain doses three times a day, with massage, was ordered. Three weeks later the vessels had become thinner, but by massage a current could be induced. At this time chloride of ammonium, in two-grain doses, was substituted for the iodide. Two weeks later the disc had become white, and the arteries thread-like. There was no movement visible. The patient then passed from under observation.

Dr. W. F. NORRIS, of Philadelphia, stated that he had had the opportunity of examining this case with Dr. Schell, and that the interrupted current in the arteries was very distinct.

The Natural History of Cataract.—Dr. ARTHUR MATHEWSON, of Brooklyn, described the case of a naval surgeon who was operated on in 1863 for cataract of the right eye, with success. The left eye was at the same time the seat of a senile cataract. He had in this eye repeated attacks of iritis, which readily yielded to atropine. Two years ago he came to Dr. Mathewson, stating that he could see better with the left eye than he previously could. An examination showed that the cataract had disappeared. The lens was afterward discovered in the anterior portion of the vitreous chamber just below the ciliary region, apparently very small, and it appeared to be fixed there. A few delicate remains of the capsule could be made

out. After correction, $V = \frac{2}{3}$. He used the eye for two years, but then began to suffer from attacks of iritis. At first these yielded to atropine. Last autumn, on one occasion when the eye was giving pain, he found that the atropine did not relieve the pain, and he came to Dr. Mathewson. At that time the eye exhibited the appearance of glaucoma. There was also a flocculent-looking mass in the lower part of the anterior chamber. A two-grain solution of eserine was now employed. This reduced the tension and cleared up the sight. There was no return of the pain for some weeks. Eserine at first gave partial relief when the pain returned, but it soon ceased to have any effect. At one time, when he was suffering very greatly, a hypodermic injection of ten minims of Magendie's solution of morphine was given. This relieved the pains and also the glaucomatous symptoms. The symptoms, however, returned in a few days, and morphine failed to relieve them. Enucleation of the eye was then decided on. When examined after removal, the lens was found to be very much attenuated, hardly 3 mm. in diameter, and very thin. There had been no injury or blow to account for the dislocation of the lens.

Dr. JOHN GREEN reported three cases in which cataract had terminated in a similar manner.

Errors of Refraction.—Dr. W. W. SEELY, of Cincinnati, read a paper giving his experience in certain cases of affection of the refraction. He laid particular stress on lack of balance of the ocular muscles, and its relation to changes of refraction; on the lesser degrees of myopic astigmatism, with or without blepharitis, with or without asthenopic symptoms; and on the state called mixed astigmatism. Very often apparent myopia or myopic astigmatism was not real, and, in order to determine this, the accommodation should be paralyzed. A number of cases illustrating the different refractive errors considered were given in detail.

Clinical History of a Case of Sympathetic Ophthalmia was the title of a paper by Dr. L. WEBSTER FOX, of Philadelphia, which, in the absence of the author, was read by the secretary. W. W. sustained a puncture of the left eye in the ciliary region. The wound was situated in the inner lower quadrant of the ball, near the cornea. The eye was treated with cold water and banded. In twenty-four hours iritis developed. The trouble went on until perception of light only remained. There was but little pain. In two weeks the boy was allowed to go to school, although the eye was still inflamed. Two days later he complained of dimness of vision in the right eye. An ophthalmic surgeon who was then consulted at once began vigorous treatment, but without benefit. When the boy was seen by Dr. Fox the left cornea was hazy, and the pupil occluded. There was still perception of light. The condition of the right eye was similar, but more pronounced. On the thickened iris new-formed vessels could be discerned. There was but little pain, but light could not be borne. As considerable inflammatory deposit remained, mercury was administered. During the next few weeks the redness disappeared, but vision was lost.

Two Cases of Orbital Abscess were reported by Dr. J. A. LIPPINCOTT, of Pittsburgh, Pa., in one of which complete recovery occurred, while the other was remarkable on account of the early age at which the disease developed. The first case was seen in September, 1877. The disease occurred in a feeble child after an attack of facial erysipelas. A small abscess of the right upper lid first formed. There was at this time no displacement of the ball nor loss of mobility, but the general symptoms were more marked than could be accounted for by the abscess of the lid. The small abscess was opened, and a few drops of pus escaped. It then rapidly healed and the patient was placed on the use of syrup of iodide of iron and quinine. Six days later a rapid protrusion of the eyeball took place, accom-

panied with a speedy increase in the general symptoms. The ball protruded more than half an inch, it was scarcely movable, and there was almost complete ptosis. The sight appeared to be unimpaired. An exploratory incision was made under the upper lid, on the inner side of the eyeball, and pus was discovered. The incision was then enlarged and a drachm and a half of thick offensive pus was evacuated. A poultice was applied in such a way as to produce pressure. The swelling and protrusion then rapidly subsided, and five weeks later the mobility of the eye had returned. After forty-eight hours an abscess behind the left ball developed. This was evacuated and rapidly healed. A recent examination of the eye showed scarcely any protrusion, a normal fundus, and perfect vision.

The second case, which was seen in the autumn of 1880, occurred in a child twelve months old. The disease could only be attributed to exposure to cold. Three weeks before the child came under observation the eyelids became greatly swollen. Two weeks later rapid protrusion of the globe occurred, accompanied with a slight muco-purulent discharge. An intra-orbital abscess was diagnosed. At the time of the examination the pain did not seem to be severe. There was a temperature of 99° F. An aspirating-needle was introduced above the globe, and dark-brown fetid pus escaped. An incision was then made and a drachm of pus allowed to escape. A poultice was applied and quinine and iron were administered. The patient gradually improved, but a week later it became necessary to make a second opening, as the first had closed. At this time thick, creamy, laudable pus escaped. Two weeks afterward the opening closed and the condition continued to improve. At present there was about one sixteenth of an inch protrusion, with considerable swelling of the lids and partial ptosis. A gelatinous mass three quarters of an inch long and a quarter of an inch wide protruded between the lower lid and the eyeball. The mobility was perfect. Vision was limited to perception of light. There was decided white atrophy of the disc, and the retinal vessels were much contracted.

Dr. S. THEOBALD said that he had recently had a severe case of abscess of the orbit, in a man run down with hard work. When he first complained of pain about the eyeball there was some chemosis, with perhaps a little prominence of the eyeball. This gradually increased, and in a few days fluctuation could be detected. An incision was made, and free discharge of healthy pus followed. The eye gradually receded. Two days after the first incision it became necessary to make another opening lower down. The exophthalmus entirely disappeared, and vision was completely restored.

Abscess of the Frontal Sinus, Ethmoidal Cells, and Sphenoidal Sinus.—Dr. CHARLES J. KIPP, of Newark, read a paper on the case of a patient who had suffered from headache for a number of years. Diplopia was observed one year before he came under observation. A nodular tumor was found involving the left orbit and pushing the eyeball downward and outward. The tumor was hard, and no fluctuation could be detected. The sight was normal. The fundus presented no special peculiarities. The diagnosis made was sarcoma with periostitis. An operation was decided on. An incision was made over the tumor, which was found to consist in part of bone. During the progress of the operation, the wall of the tumor ruptured and a large amount of fetid pus escaped. The abscess was found to extend upward and backward. The pus was removed and a drainage-tube introduced. The abscess was washed out every day. On the eleventh day after the operation the patient contracted pneumonia, and, despite careful treatment, died on the seventeenth day after the operation. At the post-mortem, the frontal sinus, the sphenoidal sinus, and the ethmoidal cells were found to have been converted into one

large cavity, from the walls of which numerous spicules of bone projected.

Dr. KIPP also described a case of **Distension of the Frontal Sinus**. The patient presented a painful swelling below the left eyebrow. This had begun to appear about six months previously, although there had been pain in this region for several years. The tumor was hard, but, on deep pressure, fluctuation could be detected. Distension of the frontal sinus was the diagnosis, and an operation was recommended. This was declined, and the case was not again seen for eight months. The swelling was then larger, the eye had become red and painful, and an ulcer of the cornea had appeared. Under treatment the inflammatory symptoms subsided. On one occasion, while the swelling was being examined, it was felt to give way, and at once there was a discharge of pus into the nose. After this the nose was frequently washed and nitrate of silver applied to the mucous membrane. The abscess was also emptied of pus every day, by means of pressure with the finger. Under this treatment the sac became distended less and less frequently, until the present time, when it rarely became enlarged.

Dr. L. HOWE, of Buffalo, read a paper on **The Changes which occur in the Eye immediately after Death**.

Thursday's Proceedings.—Morning Session.

Dr. W. S. LITTLE read a paper on **Glioma of the Retina**, double congenital. A child three months old was seen in June, 1882, and a glioma in each eye diagnosed. There was no history of syphilis. At the age of one year the child became blind. The case progressed, and recently the glands of the neck became involved. The parents would not allow any operative interference. The treatment consisted of the administration of iodide of potassium and mercury. The child died in May, 1884.

Dr. THEOBALD related a case of glioma in which he enucleated the eye four years ago. So far, there had been no return of the disease. In another case of glioma he had enucleated the eye, but the child died one year later from some affection of the brain, the exact nature of which he had been unable to ascertain. The first patient was twelve years old and the second nine years.

Dr. W. F. MITTENDORF, of New York, asked whether it was not the general experience that enucleation in glioma was simply palliative and not curative. He thought that it was unusual for the disease to develop so late as in the cases reported by Dr. Theobald.

Dr. STUPHEN, of Newark, stated that in a case which he had examined there were, with the glioma, choreic symptoms, which he thought might be due to the glioma. He enucleated the eyeball and prescribed Fowler's solution. The child recovered.

Dr. MATHEWSON remarked that some of the rare cases of non-recurrence of glioma after operation could be accounted for on the ground of faulty diagnosis, and related a case in support of this statement.

Dr. H. KNAPP, of New York, said that complete recovery undoubtedly might take place after operation in cases of true glioma. He had seen one case, and the patient was still living, fourteen years after the removal of the eye. The anatomical investigation showed beyond doubt that there was glioma.

A paper giving a partial report of the progress of the **Examination of the Employees of the Pennsylvania Railroad as to their Color-sense and Acuteness of Vision and Hearing**, by Dr. WILLIAM THOMPSON, of Philadelphia, was read by Dr. W. S. LITTLE. The paper also referred to the importance of legislative action on the subject, and described what had been done in this direction.

Dr. GEORGE C. HABLEY, of Philadelphia, read a paper describing two cases of **Swelling of the Optic Papilla**, probably congenital. The first was that of a student suffering with myopia, who consulted the doctor to find out whether or not he was wearing the proper glasses. The ophthalmoscope showed swelling of the optic nerve to the extent of 3 or 4 D. The case was examined several times afterward, and no change in the condition was observed. The second case was that of a girl fifteen years of age. She had suffered from headache and pain in the eyeball, increased by the use of the eye. There was slight hypermetropia, which was corrected, and the symptoms disappeared. There was also observed a swelling of the optic papilla, which remained the same as long as the case was under observation.

Dr. SAMUEL D. RISLEY, of Philadelphia, related the case of a young married woman who consulted him for asthenopic symptoms. He found hypermetropic astigmatism and swelling of the nerve to the extent of 2 or 3 D. The margins of the disc were decidedly obscured. The refractive defect having been remedied, the symptoms passed away. After correction, $V = \frac{2}{3}$.

Dr. MITTENDORF had examined a similar case, and had attributed the appearance to an overgrowth of the connective-tissue elements of the optic disc. There was also a fine silky appearance of the retina. This case had been under observation for more than a year.

Improvement of Vision with Rahlmann's Hyperbolic Lenses.—Dr. G. HAY, of Boston, reported two cases. In the first case the cornea was unduly prominent, and in the second there was pronounced conical cornea. In both there was decided improvement of vision.

A Case of Myxedema with Atrophy of the Optic Nerves was reported by Dr. O. F. WADSWORTH, of Boston. The patient was a married woman, forty-two years of age. She had never had any children nor any miscarriages. Menstruation had been regular until three years ago, when it ceased. The general health had been good. Six years ago the face, the lower part of the hands, and the feet became enlarged and oedematous, but did not pit on pressure. This gradually increased, but continued limited to the parts first affected. She stated that she never perspired, but the skin was not especially dry to the feel. A year and a half ago she noticed that the sight of the right eye was beginning to fail. With this eye there was now barely perception of light. With the left, vision was $\frac{2}{3}$. The discs presented the appearances of simple gray atrophy. The mental condition was good, although her friends thought that her memory was not so good as formerly. The reader had examined other cases of myxedema, but had never before seen any affection of the eyes.

Dr. LITTLE had examined seven or eight cases of myxedema, but had never seen anything abnormal with the eyes.

Acute Dacryo-adenitis was the title of a paper by Dr. THOMAS R. POOLEY, of New York. The case occurred in a girl of twenty, who had been suffering from chronic trachoma and trichiasis. Subsequently diphtheritic inflammation of the conjunctiva of the left eye appeared and caused the destruction of that eye. Three weeks later a painful swelling appeared at the outer upper angle of the right eye. Hot applications were employed and quinine and large doses of tincture of the chloride of iron were used internally. The following day an incision was made through the lid, but no pus was found. The applications were continued. The next day there was decided improvement. The hot applications were now used for fifteen minutes three times a day, and in the intervals a pressure bandage was applied. Improvement was rapid, and, when last seen, she was perfectly well and the sight was completely restored.

Dr. KNAPP did not think that unilateral inflammation of the

lachrymal gland was a rare disease. Bilateral inflammation was more rare. He had never seen inflammation of the lachrymal gland appear during the course of an infectious disease, and in the majority of cases which he had seen there had been no affection of the conjunctiva.

Dr. H. G. MILLER, of Providence, had seen one case of bilateral inflammation of the lachrymal glands, which at the time had been supposed by the family physician to be gonorrhoeal ophthalmia. The treatment consisted in the use of hot-water cloths. Under this the inflammation subsided, without suppuration, in the course of three days.

Polycoria.—Dr. MITTENDORF described two cases. One was in a lady of thirty-two. Seven years previously the sight of the right eye had been lost. She consulted the doctor for compound hypermetropic astigmatism. On examination, he found five pupils, the largest one being in the center. After correction, $V = \frac{3}{8}$. The second patient was the father of the first one. He had two pupils, the lower one being divided into two by a band passing across it. In neither of these cases had there been any deterioration of vision.

Dr. SEELY had studied a number of cases occurring in one family. In all the instances which he had seen the patient eventually became blind with choroiditis.

A Plastic Operation for Deformity of the Lids was described by Dr. E. HUTCHINSON. The patient had been injured by a premature explosion while blasting a rock. This had caused destruction of the sight of the left eye. The right eye was uninjured, but the healing of the wound had caused such contraction of the lids and the parts surrounding them that he could not open his eye. In order to relieve the difficulty, a deep incision was made through the external commissure, and the ligament was divided and dissected up. A web of conjunctival tissue was then dissected free and inserted into the opening which had been made. After this had united, the ectropion was operated on by making a V-shaped incision and bringing the parts together. A very satisfactory result had been obtained. Photographs were exhibited showing the condition before and after the operation.

Removal of Foreign Bodies from the Vitreous.—Dr. JOSEPH AUB, of St. Louis, described four cases, including three in which pieces of iron that had passed into the vitreous were successfully removed with the electro-magnet. In these cases sight was preserved. In the fourth case the magnet could not detach the piece of iron. The eye was enucleated, and examination showed the particle to be so firmly imbedded in the walls of the eye that it was impossible to detach it with the forceps until the attachments were cut.

Dr. KNAPP had come to the conclusion, from his own experience and that of others, that the best plan to pursue when the foreign body could not be seen would be to remove the globe.

A Case of Hypermetropic Astigmatism was described by Dr. RISLEY, who had seen it nine years ago. Glasses were ordered, and the symptoms complained of disappeared. Eight years later the patient returned, and an examination showed that there was then myopic astigmatism, which being corrected, the symptoms again passed away.

Dr. KNAPP thought that many of these cases of so-called astigmatism occurring in nervous girls were not real cases of astigmatism, and that under proper hygienic treatment they would get well without glasses. He thought that the majority of patients would not observe a refractive error of $\frac{1}{2}$.

Dr. THEOBALD thought that the proper indication for correcting a small degree of myopia was the occurrence of asthenopic symptoms. If these were absent, and there was no discomfort from the disproportion between the convergence and the accommodation, a slight degree of astigmatism might be neglected.

NEW YORK OBSTETRICAL SOCIETY.

A REGULAR meeting was held March 4, 1884, Dr. CLEMENT CLEVELAND, Vice-President, in the chair.

A Successful Case of Laparo-hysterectomy for Uterine Fibroids.—Dr. P. F. MUNDÉ presented a specimen, with a written report of the case, sent by Dr. ELY VAN DE WARKER, of Syracuse. [See p. 128.] Dr. MUNDÉ remarked that the case was notable in that the patient recovered, and also because of the rapidity with which the operation was done. The question as to the best manner of treating the stump had been raised in this case, as at the last meeting of the society; certainly the extra-peritoneal plan was the one which had been successful in the hands of German surgeons. Recently the elastic ligature, clamped with lead, had been allowed to remain on the stump, to take the place of the clamp, by some operators. In spite of reported successes, one could hardly conceive how inflammation and abscess would not attend the presence of a rubber tube and a bullet in the peritoneal cavity. We had learned, however, that the peritonæum at times would stand almost anything.

Removal of the Ovaries and Fallopian Tubes, followed by the Disappearance of Symptoms of Spinal Atrophy.—Five years ago Dr. MUNDÉ was requested to see a patient by Dr. Allan McLane Hamilton, she being at that time twenty-five years of age. Three years previously, while returning home one evening from a party, during the menstrual period, she was seized with what was called a fainting fit, and was unable to walk. She remained paralyzed in the lower limbs for some months. Gradually some power returned, but she remained unable to walk, being only able to put one foot a little before the other, dragging the left one as a patient affected with hemiplegia would. Dr. MUNDÉ was asked to see the patient because, at her menstrual periods, she suffered a great deal from pain in the left ovarian region and back, and from nausea and vomiting, which continued for two weeks out of every four. She became emaciated in consequence, and had been all these years a bed-ridden invalid. A vaginal examination showed retroversion of the uterus and prolapse of the left ovary. The ovary was not much enlarged, but very tender. Pessaries and other means for maintaining the womb in an improved position gave rise to pain, intra-vaginal and abdominal counter-irritation gave but temporary relief, and finally treatment was abandoned. Oöphorectomy was suggested, and the patient was anxious for it, but it was not countenanced, because Dr. Hamilton had examined the patient very carefully and found undoubted symptoms of chronic myelitis in the lumbar region of the cord. Dr. Thomas and Dr. Emmet had seen the patient before she came under Dr. MUNDÉ's care, and both had also discountenanced an operation, believing that the disease of the cord would in no way be benefited thereby. In this opinion Dr. MUNDÉ entirely concurred. During the next three years Dr. MUNDÉ saw the patient only occasionally, when she suffered more than usual from ovarian pain. Last autumn she again raised the subject of removal of the ovaries, and was more anxious than ever to have the operation performed, especially after she had been shown the report of a recent case (in the "Centralblatt für Gynäkologie") of a woman who had been for seven years in a similar condition, unable to walk and forced to take nourishment through a tube, because of continuous trismus, and who, six months after removal of the ovaries, was able to walk six miles, and made a perfect recovery. After due deliberation, Dr. MUNDÉ finally decided to give the patient the chance of possible benefit from the operation, provided a consultant agreed. Dr. Emmet again saw the patient, and he also thought that, while the operation probably would be of no benefit as regarded the ataxia, and perhaps of none as regarded the general debility and nausea, still,

as there was no other possible chance of relief before the climacteric period, nearly fifteen years hence, she might as well be given this chance, knowing, as she did, the risks. On the 6th of January both ovaries and tubes were removed, the uterus being elevated with a repositoir. No special difficulty was experienced during the operation. The ovaries were not adherent. The highest temperature after the operation was 99.5° F. The patient, who was an unusually intelligent lady, called his attention four days after the operation to the fact that she was able to move the toes of the left foot, which she had not been able to do during the preceding seven years. About a week later she was able to bend the left knee. About the fifteenth or seventeenth day she was moved to a lounge and began gradually to learn to walk, beginning like a child. Instead of dragging the left foot, as she had formerly done, she placed it directly forward in the normal manner. It was now two months lacking two days since the operation was done, and Dr. Mundé had seen the patient this afternoon, when she walked the full length of the double room without assistance, and apparently as well as anybody could. He confessed that he was surprised to see such marked improvement in the spinal symptoms. The gastric symptoms had also greatly improved. There had been no sign whatever, not even a molimen, of menstruation since the operation.

Removal of the Ovaries and Fallopian Tubes.—Dr. MUNDÉ also presented the tubes and ovaries removed a week ago at Mt. Sinai Hospital from a patient, twenty-four years of age, who had been married for three years, and for two years had suffered severely from dysmenorrhœa and from hysteropileptic attacks. Dysmenorrhœa had existed before, but in a less marked degree. The patient was unable to work, and the epileptoid attacks, which occurred at irregular intervals and as often as three or four times a week, left her in a very prostrated condition. She had been unable to obtain any relief, and was therefore very desirous of oöphorectomy. Although she had been sent to him by her physician with the express purpose of having the ovaries removed, Dr. Mundé was skeptical about the propriety of the operation until after he had had her under observation for some weeks in the hospital. While sufficient time had not elapsed to speak of the permanency of the result, it would seem that the patient would be markedly benefited by the operation. There were extensive adhesions, and considerable difficulty was experienced in removing the ovaries, but the patient was making a very good recovery; the highest temperature occurred on the third day, reaching only 100° F.

In reply to a question by Dr. J. G. Perry, Dr. Mundé said the left ovary in the first case contained three small cysts. He further said that there had been no flow, nausea, vomiting, or pain. The appetite had greatly improved. In the second case there was salpingitis.

An Instrument for Perforating Shot.—The VICE-PRESIDENT presented an instrument of this sort, devised by one of the workmen in Messrs. Caswell, Hazard & Co.'s factory.

The Treatment of Certain Cases of Retroversion of the Uterus by causing Post-cervical Adhesion.—Dr. J. B. HUNTER said there were certain cases of retroversion of the uterus, unattended with flexion, in which the malposition seemed to be due to the mere force of gravitation, so easily was the organ replaced. It seemed to him that, if in such cases the cervix could be fixed to the posterior wall of the vagina, the uterus would cease to fall backward. With this idea he had recently denuded a portion of the posterior border of the cervix and of the vaginal vault, and fastened them together with sutures. When union had taken place he would remove the sutures. The suggestion had been derived from seeing a case in which the same object was accomplished by cicatricial bands between the

posterior wall of the vagina and the cervix, following inflammation.

The Effects of a Pretended Oöphorectomy.—The cases related by Dr. Mundé suggested the following one to Dr. W. R. GILLETTE. A German girl entered St. Francis's Hospital with a history that she had been in nearly all the hospitals in the city, for severe dysmenorrhœa, pelvic pains, and epileptic seizures. She professed to live without eating, but it was found that she took bread in some surreptitious manner. The Sisters watched her very closely, and concluded that she was a hysteropileptic. Dr. Gillette found prolapse of the ovaries. The patient was very anxious to have an operation done, and her mother stated that doubtless she had been a real sufferer for several years. Dr. Gillette thought it a good case in which to try the influence of mind over matter, and made all the necessary preparations for oöphorectomy, placed the patient upon the operating-table, made an incision into the subcutaneous fat of the abdominal walls, and closed the wound. The patient improved wonderfully after the pretended oöphorectomy. He had heard, however, that she had lately had a return of the symptoms, and had presented herself at several hospitals, desiring that something more than the ovaries be removed.

Dr. MUNDÉ said that he had reported a case to the society a year ago, in which the operation was unsuccessful as regarded relief from the symptoms. The patient had since committed suicide.

Dr. W. G. WYLLIE (present by invitation) mentioned the fact that he once removed both ovaries and tubes, and the patient had menstruated regularly ever since.

Dr. W. M. CHAMBERLAIN said the case reported by Dr. Gillette was not altogether unique. He had been told by a friend that a gentleman in Brooklyn had cut into the abdominal wall nearly down to the peritonæum in a certain case, and then sewed up the wound, and that for six weeks afterward the patient was entirely relieved of dysmenorrhœa and other symptoms. He had not heard from the case since.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Meeting of June 26, 1884.

The President, Dr. TYSON, in the chair.

Specimens from a Case of Resection of the Humerus.

Dr. C. B. NANCREDE related the case of a girl, seventeen years old, from whom the specimens had been removed. On the 2d of January she received a severe compound comminuted fracture of the left humerus by having her arm wound around the main shaft of a piece of machinery in a spinning-mill. At the same time she received several severe scalp wounds. Irrigation with bichloride-of-mercury solution resulted in saving the arm, although the girl nearly lost her life. At the end of six weeks, no union having taken place, and the ends of the fragments having become necrosed, the speaker cut down upon and removed the fragments shown, and, after sawing off the ends of the main fragments, drilled and fastened the latter together with two stout silver wires. The whole limb was then put up in a plaster apparatus, which was not disturbed until irritation of the skin from pressure, etc., required it. Now, at the expiration of five months, the fragments seemed firmly consolidated, and the line of the bone was apparently perfect.

Spindle-celled Sarcoma of the Breast.—Dr. G. SCHWEINITZ presented microscopic sections from a tumor of the breast that had been removed at the University Hospital by Dr. John Ashhurst. The history, in brief, was as follows: Annie S., married, aged thirty-five, the mother of four children, had a good family history. Her own health was good until two years

ago, when she began to suffer from the effects of malaria. The tumor of the breast was first discovered one year ago, and grew gradually, without much pain, until the date of the operation, when it had attained the size of an orange. There was no enlargement of the axillary glands, and the nipple was not retracted. To the touch, the growth was hard, and in spots the skin had become adherent, giving rise to the pitted, somewhat brawny or lardaceous appearance described by surgical writers as rather indicative of scirrhus of the breast. This appearance was sufficiently marked to cause the diagnosis of hard carcinoma to be suggested as probably correct. When the mass was laid open, after its removal, both cut surfaces did not appear concave, as was usually the case with a scirrhus, and microscopic examination had cleared up the diagnosis, for, as would be seen by examining the specimens, they showed the typical appearances of a small-spindle-celled sarcoma. The case seemed a good one to illustrate the difficulties sometimes encountered in correctly diagnosing tumors of the breast, and for the reasons that had been briefly referred to.

Reports on the Progress of Medicine.

OPHTHALMOLOGY.

By CHARLES STEDMAN BULL, M. D.,

LECTURER ON OPHTHALMOLOGY AND OTOTOLOGY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE; SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY; OPHTHALMIC SURGEON TO ST. MARY'S FREE HOSPITAL FOR CHILDREN AND TO THE NURSERY AND CHILD'S HOSPITAL.

Color-Perception and Color-Blindness.—Burnett ("Arch. f. Augenheh.," xii, 2, 3), in his paper upon this subject, reviews the objections of Mauthner to the Young-Helmholtz theory of three colors, and also the results of Pfäfer's investigations. He then considers Donders's objections to Hering's theory of color, especially the objection that this theory does not explain the various forms of color-blindness. The investigation of a very large number of cases of color-blindness has led to the conviction that there are no cases of pure red, green, or violet blindness; and hence it is better to use the terms red-green and blue-yellow blindness. Neither of the two hypotheses, the Young-Helmholtz nor the Hering hypothesis, can be regarded as an acceptable or admissible theory, as neither of them is capable of explaining all the phenomena. In congenital color-blindness too much importance is attributed to the retinal elements as color-perceiving organs, without considering other factors. The perception of color is carried out by three organs: the retina, the optic nerve, and the brain as visual center. If one of these parts does not function, disturbances appear. The real theory of colors, when found, will be a simple one, which will agree with the well-known laws of the action of light upon simple bodies. From experiments upon the molecular action of light upon certain substances, it is probable that the difference in color-perception depends not upon the composition of the tissue, but upon the difference in action of the acting cause.

Cysticercus Ocularis.—Manz (*Ibid.*) reports two interesting cases of this somewhat rare disease. The first case was a subconjunctival cysticercus occurring in a man, aged sixty-five, who presented a tumor as large as a bean over the insertion of the internal rectus of the right eye. The overlying conjunctiva was somewhat injected, but freely movable over the tumor. The latter was elastic, and evidently a cyst. The conjunctiva was divided over the growth, which presented itself as a translucent cyst, which, on being grasped at the base, collapsed, and

the cysticercus, with the head and neck drawn into the bladder, was readily removed. The second case was a subretinal cysticercus, occurring in a young woman, who complained of a sudden loss of vision in the right eye some weeks before. Two weeks later there was a moderate inflammatory process, with pain in the eye; this lasted for several weeks, and then slowly subsided, and the vision improved somewhat. Vision was normal in the good eye and only $\frac{1}{10}$ in the affected eye, by extreme eccentric position of the eye. In the vitreous there was a delicate net-like opacity, which obscured the entire fundus. The outline of the disc was indistinct, its central part injected, and the retinal veins dilated. In the region of the macula lutea there was a sharply defined detachment of the retina of a grayish-white color and about four papillary diameters, the apex of which was slightly outside of the posterior pole, and the horizontal axis of which was just above the horizontal meridian. At the lower margin of the detachment was a small pouch or ectasia, and at its apex there was a sharply defined yellow spot, across which ran a small vessel. The surface was smooth in places, and in places wrinkled in small folds. The region between it and the papilla was cloudy, and the retina seemed elevated in irregular folds; in the middle of this region were two small red points. The visual field, repeatedly examined, showed normal external limits and a large, irregular scotoma downward and inward from the point of fixation, within the limits of which vision was entirely abolished. A diagnosis was made of cysticercus subretinalis, and it was decided to attempt its removal by operation. The conjunctiva was divided on the temporal side, three millimetres from the corneal margin. A thread was then passed through the tendon of the external rectus muscle, and the tendon was then divided. The eyeball was then pulled over as far toward the nose as possible, and an incision was then made in the sclera just above the horizontal meridian. As soon as the choroid was divided, a cloudy fluid escaped from beneath the detached retina. A curved pair of forceps was then introduced and directed backward, and the small bladder-bag was easily removed. There was no loss of vitreous and no hæmorrhage. The wound in the sclera was coated completely, the tendon of the muscle stitched to the sclera, and the conjunctival wound closed by two sutures. The wound healed rapidly and the sutures were removed on the third day. Vision remained about $\frac{3}{5}$.

Reflex Amblyopia and Thrombosis of the Retinal Artery.—Priestley Smith's article ("Ophthalmic Review," Jan and Feb., 1884) is of great interest, and is based mainly upon his observation of the case of a young married woman, aged twenty-four, who consulted him on August 17, 1883, on account of blindness of her left eye. In this case the pathological sequence was probably reflex disturbance of the circulation in the brain and retina through cardiac inhibition; great reduction and slowing of the blood-current in the retinal artery; thrombosis; the event being strongly favored by constitutional anæmia and feebleness of heart. The other eye ran great danger of a similar disaster; it was many times temporarily blinded by the same reflex mechanism, and presented for some weeks a marked contraction of the visual field. It was finally restored to a healthy state by the removal, by abdominal section, of both ovaries and Fallopian tubes. When the writer first saw the patient he found in the R. E. Hm. $\frac{1}{4}$ and V. = $\frac{1}{2}$; accommodative asthenopia; pupil, media, and fundus normal, and field of vision entire. In the L. E., V. nearly 0; faint perception of light in a small central area; pupil of same size as its fellow and irresponsive to direct light; media clear; disc white and well-defined; no change at yellow spot; retinal arteries shrunken to threads and for the most part empty; retinal veins a little larger than the arteries. After thorough examination of the pelvic organs by

an expert, a diagnosis was made of chronic ovaritis, with dilatation of the Fallopian tube on the left side. On November 21, 1883, abdominal section, removal of both ovaries and Fallopian tubes. Left ovary matted to left side of pelvis; the corresponding tube convoluted and distended with clear fluid; right ovary and tube intimately adherent, so that their normal relations were destroyed. Complete recovery. On December 23, 1883, examination of R. E. showed asthenopia much diminished and general condition much improved; L. E. probably somewhat improved, as she occasionally sees double. In this case the loss of sight depended more or less completely upon reflex influence. The attacks of transient blindness which the R. E. suffered may have been the expression of heart-failure merely, or they may have been due to spasm of blood-vessels, but in either case they were directly induced by reflex mechanism set in motion from the pelvis. Heart-failure was probably the chief factor, for in most of the attacks the loss of sight was accompanied by actual fainting. The condition of the L. E. showed that its blindness was caused by retinal anemia, and, inasmuch as the exciting cause and mode of onset were the same in both eyes, it can hardly be doubted that the frequent transient blindness of the right eye was also a retinal condition. The ophthalmoscopic appearances in the blind eye, two months after the sight was lost, were precisely like those which follow embolism of the retinal artery. The theory of spontaneous thrombosis is favored by the following points: 1. Previous attacks of transient blindness in the blind eye. 2. A simultaneous attack of transient blindness in the blind eye. 3. Previous or subsequent attacks of transient blindness in the fellow-eye. 4. Signs of disturbance of the cerebral circulation at the onset of the blindness, giddiness, faintness, headache. Evidence strongly in favor of embolism is probably chiefly of a negative kind: 1. Absence of transient attacks of blindness either in the blind or in the fellow-eye. 2. Absence of giddiness, faintness, or pain at the moment of onset. A second case was in the person of a married woman, aged forty, who, during the past three or four years, had had many attacks of dimness of sight. One eye suffered an attack of sudden, complete, and permanent blindness, and, when examined on the fourth day of the blindness, the eye presented the appearances which denote blocking of the retinal artery, and which are commonly attributed to embolism. The patient had valvular disease of the heart. But the idea of embolism in this case was opposed and the diagnosis of thrombosis rendered highly probable by the fact that the attack of permanent blindness had been preceded by a long series of attacks of transient blindness. In a third case, occurring in a man, aged thirty-eight, the patient was not seen until three years after the loss of sight occurred, but the ophthalmoscopic appearances allowed of no doubt that the retinal circulation had been arrested. Here there had been no failure of vision previous to the blinding attack, and the seeing eye suffered no attacks afterward. A diagnosis of embolism would meet the case completely were it not confronted by one small point in the history, namely, that for a few minutes at the onset of the blindness both eyes were blind. There was no disease of the heart in this case, and no evidence of any habitual tendency to vascular disturbance in the brain or retina. Yet the loss of sight was manifestly due to temporary arrest of the retinal circulation, for in the one eye the arteries remained permanently empty. It is noteworthy that the blindness occurred in connection with sleep after a heavy meal. It seems likely that in this case the retinal anemia was a reflex effect proceeding from the stomach. A fourth case occurred in an unmarried woman, aged twenty-five, in whom there had been many transient failures of vision. During the blinding attack both retinæ were completely involved, but the blindness proved permanent only in the lower half of one;

and there was probably some slight peculiarity in the caliber, mode of division, or bending of the lower branch of the retinal artery, which was especially unfavorable to the speedy re-establishment of the blood-stream. The fifth case occurred in a young woman, aged eighteen, who had had a number of attacks of dimness of vision of the right eye, during which the lower half of objects was lost. The attacks always came suddenly and always in one eye. The ophthalmoscopic appearances were normal, with the exception that the vein in the upper half of the right retina was rather engorged. The explanation of this transient hemiopia is probably to be found in some transient cause of diminished blood-flow, more pronounced in the upper half of one retina than elsewhere, owing to some peculiarity in the upper branch of the retinal artery favorable to a reduction of the blood-supply. The sixth case was in a woman, aged twenty, under the care of Mr. Streetfield. Here there was permanent blindness of the upper half of one retina, which depended upon the obliteration of the upper division of the retinal artery. In this case the probability leaned rather toward embolism than thrombosis, as simultaneous failure of both eyes at the onset was wanting. In favor of thrombosis was the fact that there had been transient failures of vision before. There was organic disease of the heart. The seventh case occurred in a woman, aged seventy, who complained of blindness in her left eye. Here there was arterial degeneration, but no valvular disease of the heart. The fact that the blindness yielded twice to rubbing of the affected eye, but returned a third time on the following day, is opposed to the idea that the artery was obstructed by an embolus brought to it from a distance. The author's conclusions from his own observations are as follows:

1. Blocking of the retinal artery is due, in a considerable proportion of cases, to spontaneous thrombosis.
2. The causes of this accident are heart-failure, either from disease of the heart itself or from other causes; spasm of the blood-vessels; disease of the walls of the vessels; alterations in the quality and amount of the blood.
3. Thrombosis may be distinguished from embolism by a history of transient failures of sight resembling the permanent attack in mode of onset, and especially of simultaneous failure of the fellow-eye at the moment of onset; also by a history of faintness, giddiness, pain in the head, or other sign of circulatory disturbance at the moment of onset.
4. A distinction between the two causes is important in relation to prevention and immediate treatment of the attacks.
5. The contraction of the visual field met with in neurasthenic asthenopia is the expression of an impaired nutrition of the retina, not of a central disturbance.

Ophthalmia in the Course of Acute Articular Rheumatism.—Terrier ("Archives d'ophtalmologie," Jan.-Feb., 1884), from his observations on this subject, draws the following conclusions: 1. Primary acute articular rheumatism may be accompanied by ocular lesions, by rheumatic ophthalmia, though such cases are rare. 2. These lesions are sometimes in the conjunctiva, sometimes in the cornea, and sometimes in the uveal tract. In some cases these different structures are attacked successively in the same case. 3. These ocular symptoms or lesions may coincide with or alternate with inflammatory exacerbations in the joints. 4. In the published observations, the ophthalmia was sometimes acute, but the prognosis is in general favorable. 5. The treatment is that of general acute rheumatism.

Congenital Hemeralopia.—Chibret (*Ibid.*) reports an extraordinary case of this nature occurring in a young man, aged sixteen, in whom he found $M \frac{1}{2}$, $V = \frac{2}{3}$, and congenital hemeralopia. The visual field was very slightly narrowed, and the color-perception was perfectly normal. The fundus showed a moderate posterior sclero-choroiditis in both eyes. No other member of the family was affected in the same way.

A Perimeter of Precision.—Maklakoff (*Ibid.*) gives a detailed description of a perimeter devised by himself, for which he claims great advantages. Instead of Landolt's graduated semicircle, there are two semicircles of the same dimensions which decussate at an angle of 90°, having a common center in the same point as in Landolt's instrument. The free extremities of these semicircles are united by a frame-work resembling the skeleton of a hemisphere, represented by the equator and by two meridians which cross at right angles. The semicircles are but one centimetre in width and are turned toward the spectator, not by their surfaces but by their edges, so that they appear to the observer like a line. The degrees are marked on their surfaces, and the whole is dull black. The point of fixation is in the center. In order to control the direction of the eyes of the patient, the instrument is provided with a movable rod which carries at one end a small fork, and is fastened to the floor of the instrument, so that, when erect, the fork occupies the center of the sphere. The entire skeleton may be moved in the same way as the graduated semicircle of Landolt's perimeter is. Thus the limits of the visual field may be determined in four directions at the same time.

Embolism of the Retinal Artery.—Hirschberg ("Centralbl. f. prakt. Augenheilk.," Jan., 1884) reports a case in detail, and gives some critical remarks upon the differential diagnosis. The patient was a man, aged forty-five, who had, six months before Hirschberg saw him, suffered from violent pain in the head, which passed off after a few weeks. On the morning of the day of his first visit to Hirschberg the vision of the right eye became dim, and in about an hour and a half he became entirely blind in this eye. Four weeks previously he had had a similar attack, which did not lead to absolute blindness. He is short of breath and complains of cardiac palpitations. The left eye was normal, with the exception of a slight degree of hypermetropic astigmatism. The right eye was absolutely blind, and showed the signs of embolism of the central retinal artery, with retinal oedema and narrow arteries. There was no visible blood-current in the retina. The urine was normal. There was a systolic murmur at the apex. The retinal oedema increased, and on the next day there was a small red spot at the macula. The papilla was opaque, pale red, and indistinct in outline. The arteries were small and the veins enlarged with interruptions in the blood-column. From day to day the retinal oedema increased, being most marked between the yellow spot and the disc, giving the impression of a grayish-green or grayish-blue color. On the fifth day a slight current in the arteries was noticeable. From this time on there was a gradual improvement in the fundus of the eye, though the vision remained completely abolished. In October of the same year the patient entered the general hospital, complaining of pain in the head, elbow, ankles, and chest. There were a systolic and a diastolic murmur over the sternum. In the right eye the optic nerve was white, the arteries were very small, and the macula surrounded by a white spot. On January 23, 1883, there was a sudden febrile attack, followed by a bloody, purulent expectoration. The urine contained albumin, red-blood corpuscles, and granular casts. On February 14, 1883, there was another febrile attack, shortly followed by collapse and death. At the autopsy both ventricles of the heart were found hypertrophied, and the cardiac muscular tissue showed extensive fatty degeneration. The aortic valves were enormously thickened and very much shortened. In both lungs there was moderate alveolar distension. The spleen was three times the normal size. The kidneys showed numerous large superficial hæmorrhages, ecchymoses in the cortical substance. The liver was extensively adherent to the diaphragm. The optic papilla showed a deep atrophic excavation, reaching to the lamina cribrosa. In the retina there was

entire absence of the nerve-fiber layer and ganglion-cell layer; enormous oedema of the inter-granular layer, but no change in the bacillar layer. The orbital portion of the optic nerve was practically normal, though the nuclei of the perineurium were increased in number. The inter-vaginal space was free. The central artery and vein of the retina, so far as they ran in the nerve-trunk, appeared entirely unchanged. As regards diagnosis, two theories are to be considered: 1. The four main branches of the central retinal artery were suddenly and simultaneously blocked by an embolus. This assumption is forced, and is set aside by a microscopical examination of the retina. 2. There was an embolus of the central artery close to the point of its origin from the ophthalmic, outside the sheath of the optic nerve, in a place which remained in the cadaver and was not examined. Is this possible without causing changes in the internal coat of the arteria centralis within the optic nerve, a few millimetres from the position of the embolus?

Miscellany.

THERAPEUTICAL NOTES.

The Comparative Action of Coca and Caffeine.—In view of the remarkable discrepancy between the published statements of various observers as to the action of coca, a writer in a recent number of the "Ephemeris of Materia Medica," etc., has entered upon a course of experiments with several drugs reputed to have very much the same physiological action, and all characterized by the property of preventing sleep under certain circumstances. It is generally admitted, and is probably true, the writer remarks, that the same power in these agents which refreshes, recuperates, and sustains, in the condition which needs or requires such effects, also counteracts the tendency to sleep, or produces wakefulness when a tendency to sleep exists, and, therefore, if a tendency or disposition to sleep could be prevented by these agents, this tendency might be used as a measure of their effects when used in varying quantities, and thus the agents be measured against each other for dose, or quantitative effect. The proposition was to first measure coca against tea, then coffee against guarana, and finally to compare the four agents, using pure caffeine as a kind of standard to measure by.

An opportunity for such trials occurred in a healthy individual sixty-five years old, not habituated to the use of either tea, coffee, tobacco, or any other narcotic substances, of good physical condition and regular habits, and not very susceptible or sensitive to the action of nervines or so-called anti-spasmodics. Quantities of preparations of valerian, asafetida, compound spirit of ether, etc., which would yield a prompt effect upon many individuals seemed to have little or no effect upon him, nor did moderate quantities of wine or spirits stimulate him. In short, he had not a very impressible nervous organization, was not imaginative, nor very liable to accept results on insufficient or partial evidence. Fully occupied with work, both physical and mental in due proportion, for more than ten hours every secular day, when evening came he found himself unable to read long, on account of a drowsiness supposed to be of a purely physiological character. With a full breakfast at about 7.30, a full dinner at about 2.30, and a light evening meal about 7, and no stimulants or tea or coffee at any time, he found, as a matter of not invariable but general habit, that by half-past eight drowsiness became so dominant that it was almost impossible, and generally impracticable, to avoid falling asleep in his chair while attempting to read, even though ordinary conversation was carried on around him.

The first trial to combat or prevent this drowsiness was made with caffeine. The first specimen used was a very beautiful article made by Merck, of Darmstadt, and after that pure specimens made for the purpose, the two kinds being found identical in effect.

Beginning with a one-grain dose at about 6.30 P. M., on alternate evenings, leaving the intermediate evenings in order to be sure that the

nightly tendency still persisted, and increasing by half a grain each alternate evening, no very definite effect was perceived until the dose reached $2\frac{1}{2}$ grains, and this dose simply rendered the tendency to sleep resistible by effort. After an interval of three evenings, with the tendency to sleep recurring with somewhat varying force each evening, a dose of 3 grains was taken—the maximum single dose of the German Pharmacopœia. This gave a comfortable evening of rest, without sleep or any very strong tendency to it until ten o'clock. Without anything to counteract sleep, the rule was to read with difficulty by nine, without much comprehension by a quarter past nine, and either be asleep or go to bed by half-past nine. The 3-grain dose of caffeine repeatedly obviated all this discomfort up to ten o'clock, but did not prevent the habitual prompt and sound sleep from the time of going to bed till morning.

This was the model established, upon and by which to measure all the other agents, and they were never taken nearer than on alternate evenings, with occasional longer intervals, especially when the final doses of record were to be taken.

The next agent tried in precisely this same way was coca, and, as it was known that the quality of that which was attainable was very low, the commencing dose of the leaf in substance was 2 drachms, or about 8 grammes. This gave no very definite effect, but $2\frac{1}{2}$ drachms did give a definite effect, and a subsequent dose of $2\frac{1}{2}$ fluidrachms of a well-made fluid extract of coca gave about the same effect as $2\frac{1}{2}$ grains of caffeine. Three fluidrachms of the fluid extract were about equivalent to 3 grains of caffeine.

The writer's investigation of coca is not yet finished, but he has abandoned it for the present.

The Action of Adonis Vernalis on the Circulation was the subject of an elaborate paper, by Dr. Altmann, read at a recent meeting of the Berlin Verein für innere Medizin ("Deutsche Medicinal-Zeitung," July 10, 1884), which concludes as follows: The *Adonis vernalis* is a heart-regulating medicine in the same sense that digitalis is; it increases the power of the heart, retards its action, and heightens the arterial pressure; it quickly gives rise to increased diuresis; the indication for it is the same as for digitalis; it operates more rapidly than digitalis, and has no cumulative action; it often works where digitalis is ineffectual.

A Palatable Solution of Benzoic Acid is proposed by M. Pierre Vigier, in a recent number of the "Gazette hebdomadaire de médecine et de chirurgie":

Benzoic acid.....	1 or 2 parts;
Distilled cannella water.....	50 "
Syrup of tolu.....	100 "
Distilled water.....	850 "

Dissolve the acid in the water, and mix. A tumblerful to be taken during the twenty-four hours. For the benefit of those who dislike a sweet taste, the writer quotes another formula, by M. Laboulbène, which is essentially the same, except that the syrup of tolu is replaced by brandy.

The Treatment of the Premonitory Diarrhea of Cholera is the subject of a communication in the same journal, by M. Lereboullet. He lays stress upon the importance of promptly treating any digestive derangement, and especially any diarrhea, when cholera is prevailing, and advises the use of from twenty-five to thirty drops of paregoric after each stool, with or without ten or fifteen drops of the following mixture:

Ethereal tincture of valerian.....	10 grammes;
Sydenham's laudanum,	
95-per-cent. alcohol, each.....	5 "
Essence of peppermint.....	15 drops.

A Laxative Decoction.—The following decoction is highly recommended by a writer in a recent number of the "Memorabilien": A tablespoonful of a mixture of equal parts, by weight, of senna leaves, frangula bark, and licorice root is to be boiled for ten minutes in a pint of water. One half is to be drunk in the morning, and the other half at night. The latter portion may be allowed to stand without straining, and, should the morning portion have acted sufficiently, may be kept for the next morning. This decoction is particularly recommended as a "spring physic" (*Frühjahrskur*), as it can be taken daily for weeks

together, is not open to the objection of distending the intestine with gases and disturbing the digestion, like mineral waters, and is so agreeable to the taste that ladies take it willingly.

The Berlin Poliklinik.—The "Glasgow Medical Journal" learns that the clinical courses, comprising all the different special branches, for practical physicians, are held every month in the Poliklinik at Berlin, Carlstrasse 30. The courses always commence on the first weekday of the month. They last a whole month and are held every working-day. The number of participants is limited to six for every course. Should more than six apply for the same course, an extra or parallel course will be formed. To all those physicians who wish to perfect themselves in a special branch the opportunity is given to serve three months as assistants in that particular branch. Those gentlemen who have served as assistants will be allowed, in appropriate cases, to conduct the extra or parallel courses. It is intended to constitute the Berlin Poliklinik an international medical school for the improvement of physicians of every country. In order to have the courses conducted in foreign languages, assistantships will be conferred on foreign physicians.

The Late Dr. William Fruitnight.—The following sketch of Dr. Fruitnight has been prepared by one of his fellow-members of the Northwestern Medical and Surgical Society:

Dr. Fruitnight was born of German parents, April 20, 1858, in New York city. His education was obtained in the public schools of the city, where he passed the various grades, graduating from the grammar department. He entered the College of the City of New York, where he was graduated A. B. in the class of 1878, after which he entered upon the study of medicine with his brother, Dr. J. Henry Fruitnight, and Dr. C. A. Leale, and subsequently with Dr. J. E. Winters, and at the Bellevue Hospital Medical College, where he received his medical degree in 1880. Subsequently he successfully passed a competitive examination for an appointment on the house staff of Bellevue Hospital, where he served out his full term.

While in that service he never wavered in the fulfillment of any professional duty which he was called upon to face, and yet his convictions were always superior to formally expressed rules of action, wherefore he was very often guided by the dictates of his conscience, even though they might conflict with such prescribed regulations. When he had charge of the erysipelas pavilion he greatly overtaxed himself, and, like many of his predecessors, became a victim to septic infection, which most probably led to the ultimate cause of his early death. After leaving the hospital he became associated in practice with his brother, and was rapidly obtaining an extended practice, particularly in obstetrics and gynecology.

For a short time he was associated with Professor W. G. Wylie in the New York Polyclinic, in the department of diseases of women. He was also for a short time associated with Professor Louis Elsborg, in the department of laryngology, at the same institution. He was (also for a short time) connected with St. Elizabeth's Hospital.

He was a member of the council of the Bellevue Hospital Medical College Alumni Association, and a member of the Northwestern Medical and Surgical Society, in meetings of which he always took an active part, participating in all the scientific discussions. He was also a member of Empire City Council of the Royal Arcanum, No. 557, of which council he was the medical examiner. While he was studying medicine he taught in several of the evening schools of the city.

His death was very sudden, occurring about 11 A. M. on Sunday, July 20, 1884, at his late residence. He had fulfilled numerous professional duties on the day before. On the preceding evening he had a very difficult and complicated case of instrumental labor, which caused him much anxiety and great expenditure of physical strength. The cause of his death was cerebral thrombosis, the sequel of pachymeningitis. His obsequies were held at the residence of his brother on Tuesday evening, July 22d, the Rev. Dr. J. D. Wilson officiating. His remains were interred at Woodlawn Cemetery on the following day in the presence of his family and a circle of friends, together with delegations from the Northwestern Medical and Surgical Society and Empire Council of the Royal Arcanum.

Original Communications.

A CRITICISM OF

DR. FORMAD'S PRINTED STATEMENTS
AND CONCLUSIONS CONCERNING THE
ÆTIOLOGY OF TUBERCULOSIS.

By EDWARD O. SHAKESPEARE, A. M., M. D.,

PHILADELPHIA,

OPHTHALMIC SURGEON AND PATHOLOGIST TO THE PHILADELPHIA (BLOCKLEY)
HOSPITAL, ETC.

THE "New York Medical Journal," in its issue of June 14th of this year (p. 675), contains a report, substantially correct, of the remarks of Dr. Shakespeare during the discussion before the Philadelphia County Medical Society of Dr. Formad's second paper on "The Ætiology of Tuberculosis." In that discussion the remarks of Dr. Shakespeare were limited to three points: the statements made by Dr. Formad of Koch's animus and present views, and a consideration of Dr. Formad's theory concerning the condition of the lymph-spaces in the scrofulous.

In the issue of the same journal of June 28th appears (p. 723) a quite characteristic letter from Dr. Formad, written from the Pathological Laboratory of the University of Pennsylvania. In that letter are certain disclaimers and denials of responsibility for misrepresentations of Koch's present views and animus, with which he was charged during the above-mentioned discussion before the Philadelphia Medical Society.

It is to be remarked that it is a little odd that these disclaimers and denials have been addressed to the readers of the "Journal" rather than to the members of the society before whom his address was delivered. Perhaps, however, those who heard Dr. Formad as he delivered his address, seeing him refer only occasionally to the notes at his side, and also heard at the close of the debate a most positive reiteration of the statements which had been criticised by Dr. Shakespeare, can readily appreciate the reasons which may have caused the author of the letter to address a denial to the readers of the "Journal" rather than to themselves. If, after mature reflection, aided no doubt by the recent appearance of the second volume of the "Mittheilungen aus dem kaiserlichen Gesundheitsamte," in which Koch has declared his present views concerning the tubercle bacillus, Dr. Formad has found it necessary to retract what he said before his audience in Philadelphia in misrepresentation of those views, it would have been manly, honorable, and praiseworthy for him to do so in a straightforward manner. But he has preferred to deny his words, and to address this denial to those who did not hear them. Probably those few of the readers of the "Journal" who did hear the author's words, and have also read the printed article, will not only be struck with the vast difference between some of the oral and the printed statements, but also will be surprised at the declaration that the quotation given in his letter contains *all* that he has ever spoken or published upon that point. The remarks which Dr. Shakespeare

made before the Philadelphia society during the debate were in criticism of statements *orally addressed to the ears* of that body, and not in criticism of what had been for the most part rewritten and prepared for publication many weeks after the address was delivered. But, unfortunately for the author of the letter, there is sufficient basis, even in the greatly modified and tempered language which he quotes as his own, upon which to ground a charge of misrepresentation.

The charge which the author of the letter denies and to which, in his own language, he pleads "*not guilty*," is substantially reported by the recorder as follows:

"2. The author had further announced that Koch had so far modified his views that he now admitted that neither the form, size, and aspect of the tubercle bacillus, nor its want of individual motion, nor its peculiar behavior toward staining-fluids, distinguished it from many other bacilli." ("New York Medical Journal," June 14, 1884, p. 675.)

The language quoted by our author as his genuine and only utterance, and which he thinks to justify his denial, comprises the following sentences: "Koch seems now to lay more stress upon this low-power appearance (the S shape of the culture colonies), and upon the pathogenic properties of the bacillus tuberculosis, as a distinguishing feature from other bacilli, than upon the color test. During the conversation he admitted that some other bacilli may also yield the same micro-chemical reaction as the tubercle bacilli, but insisted that the latter can not be stained brown."

It may not be necessary to reproduce here the actual words in which Koch has expressed his present views, since they have probably by this time been read by every one interested in them. It may, however, be profitable, for more purposes than the present, to render the following into English, as an offset to the representations of the author of the letter:

Speaking of the peculiar action of Ehrlich's special staining method upon the tubercle bacilli and their surroundings, Koch says: "But in the differentiation of the tubercle bacillus this peculiarity (staining the tubercle bacilli a color in contrast to that of their surroundings) renders still further assistance, for not alone do the connective-tissue constituents assume the contrast color, but all other bacteria at present known to me, except the lepra bacillus, later to be mentioned, likewise stain by Ehrlich's coloring method in contrast to the tubercle bacilli. . . . Recently I have tested Ehrlich's method of staining upon numerous substances containing bacteria, such as putrid meat-infusion, decomposing urine, blood, and milk, foul vegetable infusions, swamp-slime, etc., but have never found bacteria which gave the same color-reaction as the tubercle bacilli. I must therefore regard all assertions concerning the occurrence of bacteria which may have been found in sputum, in putrid fluids, intestinal contents of healthy men, swamp-slime, and stained like the tubercle bacilli, as erroneous and dependent upon a faulty application of the method of staining." ("Mittheilungen aus dem kaiserlichen Gesundheitsamte," zweiter Band, Berlin, 1883, p. 12.)

"Besides the tubercle bacilli, there is at present only one

single species of bacterium known which colors in a manner similar to the tubercle bacilli. This is, as I mentioned in my first communication, the lepra bacillus. This fact is the more noteworthy since not only are the parasites of tuberculosis and lepra in manifold respects similar and apparently nearly related, but it is also known that both diseases, even anatomically as well as ætiologically, stand very close together. Of course, the staining qualities of both are not perfectly identical. For, while the lepra bacilli can be colored by the same staining fluid as can the tubercle bacilli, yet the reverse is not the case. The former, as is known, imbibe Weigert's nucleus-coloring material, as Neisser first pointed out, while the latter do not. Notwithstanding the great similarity of these two species of bacilli, still one is able to differentially diagnose each of these two forms of bacilli by means of their different behavior toward Weigert's nucleus-coloring fluid." (*L. c.*, p. 13.)

It is by no means our intention to enter upon an exhaustive criticism of those papers. Neither does time or inclination serve for such a task, for, judging from the abundance of material presented, it might prove almost interminable. Yet the position which their author occupies in this country as the demonstrator of pathology and lecturer on experimental pathology in one of the greatest of our medical schools would seem to entitle him to speak with authority upon the subject of which he writes, and would also seem to enable him to exert no little influence in the development of public opinion concerning those matters. Moreover, he claims to be a leader among the few who, from the standpoint of personal observation and experiment, have denounced Koch's claims for the agency of the tubercle bacillus in the ætiology of tuberculosis, as the following expression appears to indicate: "The only men who attempted to repeat Koch's experiments, besides the work done in the Pathological Laboratory of the University of Pennsylvania, were Spina and Watson Cheyne." (*Philadelphia Medical Times*, Feb. 9, 1884, p. 339.) Furthermore, in the stand which he has taken with regard to the question of the ætiology of tuberculosis the author is undoubtedly upon the side of prevalent professional opinion in America, and perhaps also of widespread popular belief.

All these considerations would appear to justify a careful and extended review of our author's knowledge and opinions concerning the ætiology of so fatal and widespread a disease as tuberculosis. Besides, the incalculable importance to the whole human race, for this and all future time, of Koch's discoveries, if they be confirmed; the skill, reliability, and experience of Koch in the investigation of minute organisms which may be the germs of disease; and the abundant, almost overwhelming array of strong, exact, and convincing proof, both original and confirmatory, which has been brought to the support of this new theory—make it the bounden duty of every physician, who would properly regard his obligations, not only to searchingly scrutinize the proofs upon which this theory rests, but also at the same time to most rigidly examine the ground upon which its antagonists stand.

There is, therefore, no occasion to apologize for present-

ing either a partial or a complete examination of Dr. Formad's opinions concerning tuberculosis.

In the course of his remarks in discussion of the author's last paper, as appears by the record published in the "*Journal*," the writer took occasion to state that there were very many points assumed as demonstrated, and positive statements advanced in the elaboration of this paper, which he believed to be without sufficient foundation. The letter of Dr. Formad has already been spoken of as characteristic. It is in some degree also characteristic of his already published papers upon tuberculosis, as will perhaps shortly appear. In the following incomplete review, by quoting the author against himself in refutation of some of his important assertions and conclusions, and by quoting the words of other authors in refutation of assertions and conclusions for which he has made them responsible, the endeavor will be made to show that our author has not only misrepresented other authors than Koch, but that he has repeatedly, even in the most important matters, misrepresented and flatly contradicted himself. Furthermore, it will be shown, by evidence which the author can not successfully repudiate, that he has misrepresented the extent and character of observations reported. Fully appreciating the gravity of such charges against the publications of one who would authoritatively treat of the ætiology of such a disease as tuberculosis, we now proceed, as far as space and time will permit, to substantiate them.

Toward the end of his second paper on Tuberculosis, Dr. Formad submits "a brief analysis and summary of experiments made and evidence offered in relation to the question of the parasitic origin and specific nature of tuberculosis."

Apropos of this, he continues as follows: "For the establishment of a theory in regard to a parasitic origin of a disease by means of experiments upon animals, etc., the following propositions must be affirmatively decided:

"1. *The disease produced experimentally in animals by means of inoculation with products of human disease must be proved to be identical with the disease occurring spontaneously in man.*" (*Phila. Med. Times*, April 5, 1884, p. 488, right column, par. 3.)

The author thus concludes the consideration of this proposition: "The proof, then, upon this point—the supreme one for the settlement of the question of the nature of tuberculosis—is yet to be furnished." (*L. c.*, p. 490, par. 1.)

What are the grounds upon which this conclusion is based, and how is it arrived at?

In partial conflict with the foregoing conclusion are the following words of the author found in the sentence immediately preceding: "Judging from my own experiments, there is to my mind no doubt that some forms of artificially induced tuberculosis in animals acquire gradually characters which make them identical with spontaneous tuberculosis in man or beast." (*L. c.*, p. 489, right column, par. 5.) In complete conflict with this conclusion are the following statements of our author: "In my previous studies, judging from the literature alone, I was fully impressed with the idea that tuberculosis had a specific exciting cause, and that it could be induced by inoculation with tuberculous materials. Moreover, having made numerous inoculations

with tuberculous matter, I convinced myself of this fact. . . . But at the same time, after repeating, under various modifications, the well-known control experiments, I found that, beyond doubt, even true tuberculosis could be produced by substances other than tuberculous." (*L. c.*, p. 493, right column, pars. 4 and 5.) "There is no doubt that Koch's tubercle bacillus, when isolated and cultivated for many generations and then inoculated into certain animals, is capable of inducing tuberculosis, or a nodular eruption not distinguishable from it, more readily than other irritants, so far as tried." (*L. c.*, p. 491, right column, par. 4.) "Although the tubercle bacillus is more liable to excite tuberculosis in an already inflamed and ill-nourished soil than all other simple irritants so far tested, it (the bacillus) might be readily substituted by other irritants." (*L. c.*, p. 493, left column, par. 2.)

We fail to rightly understand the meaning of language and the common methods of ratiocination and sequence of thought if the man who uttered these expressions did not believe in the undoubted identity of human tuberculosis and that produced experimentally in animals. In further conflict with this conclusion is the following statement of the author: "Spontaneous animal tuberculosis is unquestionably identical with human tuberculosis. There are a few morphological specializations which I mentioned in a former chapter—e. g., in tuberculosis of birds and in bovine tuberculosis, or pearl disease; but the essential peculiar histological features are the same in all. Tubercle bacilli appear also to be present in nearly all cases of spontaneous animal tuberculosis. I detected bacilli in a tuberculous bronchial lymph-gland from a phthisical tiger, which I had kept in alcohol for eight years, and in one from a monkey of more recent date; and several times I found bacilli in spontaneous bovine, chicken, rabbit, and guinea-pig tuberculosis. I also studied tuberculosis in the bear, lion, leopard, and in a large variety of apes (dead of phthisical consumption from the Zoological Garden), with results identical with those obtained from studies in man. But this was long before the outbreak of the *bacillary campaign*, and, consequently, Koch's parasite was not looked for in these latter cases." (*L. c.*, March 22, p. 453, right column, par. 5.) Possibly the rabbits which the author has so frequently chased may be responsible for this extraordinary doubling.

It may, perhaps, not be necessary to go further into an examination of the manner in which the conclusion as to the first proposition has been reached. But it may be at least interesting, and possibly also instructive, to the plain, straightforward, common-sense student of medicine to learn something more of the mysterious ways by which an uncommon mind grasps conclusions.

Our author views his first proposition from three different standpoints, in the order here mentioned, viz., inoculation, inhalation, feeding. Let us for convenience reverse this order and commence with the last, viz., *feeding*.

We quote one of our author's arguments in support of his already-mentioned conclusion: "The following deserves a passing mention. According to Orth (Virchow's 'Arch.', vol. lxxvi) and Bollinger ('Arch. f. exper. Path.', vol. i),

there is some doubt as to the identity of human and animal tuberculous."

Let us see whether or not these authors are responsible for that statement.

Professor J. Orth ("Experimentelle Untersuchungen über Fütterungstuberculose," Virchow's "Archiv," vol. lxxvi, p. 234), says: "I hesitate not for this affection [he is speaking of the disease produced in animals by feeding with tuberculous matter] to claim the name of tuberculosis. These irregularly eroded ulcers which proceed from caseous degeneration of minute nodules, these cheesy nodes formed by the confluence of cheesy nodules, these minute, isolated nodules themselves, with their reticulum and their many nucleated giant-cells—what else should they be other than tubercular ulcers, tubercular aggregations, isolated young tubercles, even if they are compared with human tuberculosis?"

And again, speaking of the constitution of nodules (p. 235), Orth says: "... all the nodules in my rabbits possess these characters; there exists, therefore, such a correspondence between the affection found (artificial animal tuberculosis) and human tuberculosis as can scarcely be imagined to be greater."

In his concluding remarks (p. 242), Orth says: "The possibility of contagion in animals once proved, there is the further conclusion also justified that contagion in man may be substantiated, . . . for I have already shown that tuberculosis in man and *Pertusucht* (bovine tuberculosis) must, according to their nature, be looked upon as identical diseases."

Now let us turn to the other authority mentioned by our author.

Professor O. Bollinger ("Ueber Impf- und Fütterungstuberculose," Arch. f. exper. Path., vol. i, p. 363), as one of the conclusions drawn from his own experiments, says: "Inoculation with tuberculous matter from man produces in the dog a genuine miliary tuberculosis of the pleura, lung, liver, and spleen; usually, however, in carnivora no reaction at all, or only a local inconsiderable effect, is produced."

Apropos of a miliary tuberculosis of the peritonæum, liver, and lung, induced in a goat by combined inoculation and feeding with cheesy matter from the tuberculous lung of a cow, Bollinger (p. 360) says: "Corresponding with the resemblance of the macroscopic appearance to miliary tuberculosis of the human peritonæum, the microscopic examination of the miliary eruption yielded a perfectly analogous and identical structure."

Furthermore (p. 369): "As to infectiousness, tuberculous material from man and cow appear to be very similar." And again (p. 370), speaking generally, he says: "In agreement with the gross resemblance, the tubercle, produced by inoculation and by feeding, of the dog and the medium-sized domestic animals is also histologically identical with human tubercle."

A foot-note (p. 371) reads: "I have lately had an opportunity to observe a classic spontaneous miliary tuberculosis of the lung of a sheep, which in no manner differed from that of man."

The last words we will quote from Bollinger are found upon p. 371: "If direct infection experiments upon man are at the present time wanting, nevertheless tuberculosis of the human intestines, which occurs secondarily in tuberculosis of the lungs, affords such an important analogue of the results of feeding experiments, and therewith so striking an example of self-infection through the swallowing of sputa, that one can, with great probability, admit the possibility of an infection by importation of the virus with the food."

So much for the real words and opinions of Orth and Bollinger as they themselves have expressed them in the papers referred to by our author. It might not be entirely out of place to remark that they also were written before the "bacilliary campaign" was inaugurated by Koch. We might modestly suggest that here is another opportunity for the author to display his unchallenged ingenuity. Which will he prefer? To retract his assertion, to deny his own words, or to insist that Orth and Bollinger never wrote as they did?

The next standpoint, in the reverse order above mentioned, from which our author considers his first proposition is that of *inhalation experiments*. Still pursuing our original plan, we first quote the argument of our author:

"Tappeiner's induced inhalation tuberculosis of dogs (Virchow's 'Arch.,' lxxiv, 1878, and lxxii, 1880), so much relied upon by Koch and others for the establishment of the mode of the spreading of phthisis, and partly of the bacillus doctrine itself, has been proved to be a fiction. Tappeiner, as so often quoted, subjected dogs to an atmosphere heavily charged with phthical sputum, so that the dogs were nearly bathed in the latter (known to contain bacilli) for weeks. But, in spite of this, the animals grew fat, if anything, and, after the lapse of a certain time, acquired local pulmonary affections in the form of nodules, not likely to have been tubercular in their nature, of which only in one case were some observed in the liver and kidneys.

"The experiments of Schottelius (Virchow's 'Arch.,' lxxii, 1878, and xci, 1883), Wargunin and Rajewsky ('Vratsch,' No. 6, 1882), Weichselbaum ('Centralblatt,' No. 19, 1882), and others, and my own experiments also (to be reported subsequently), make Tappeiner's assertions perfectly untenable. Tappeiner's own account of his experiments, and the microscopical description of the structure of Tappeiner's 'tubercles' by Grawitz and Friedländer in Virchow's Institute, clearly indicate that he had nodular broncho-pneumonic foci, and not tubercles." ('Phila. Med. Times,' April 5, 1884, p. 489, bottom of left and top of right column.)

Let us examine some of these statements and see how our author contributes to "the proof" that "Tappeiner's induced inhalation tuberculosis of dogs" is "a fiction." His objections to Tappeiner's experiments and conclusions appear to embrace four points: *a*, that the dogs were bathed for weeks in an atmosphere heavily charged with sputum; *b*, that they grew fat, and only in one instance showed disease of other organs than the lungs; *c*, that the disease produced was not tuberculosis, but broncho-pneumonia; *d*, that other experimenters (including himself) have produced broncho-pneumonia by inhalation of indifferent substances. Turn-

ing to the records, we see how truthfully our author has represented them.

Opposite the first point, *a*, we place the record of Tappeiner's experiments.

Tappeiner ("Ueber eine neue Methode Tuberculose zu erzeugen," in Virchow's "Arch.," Bd. 74, 1878, p. 394) says: "For all the experiments, the sputa were obtained from persons who were afflicted with tuberculous cavities of the lungs; from a teaspoonful to a tablespoonful thereof an emulsiform but transparent fluid was secured by dilution with 300 to 500 ccm. of water, which was conveyed to the experimenting-box by means of a steam atomizer attached to the outside. For experiments 1 to 8, the (inhalation) box—the dimensions of which were 1.12 metre in depth, .82 metre in breadth, and .86 metre in height—was open upon one side, being closed only by means of a grating, before which during the inhalation itself a waxed linen curtain was hung. Through a hole in the latter the stream from the atomizer entered the box. In experiments 1 to 4 the animals were subjected to inhalation twice daily for one hour at a time, and they remained the rest of the time in the box; in experiments 5 to 8 they were subjected to inhalation barely once daily, and the rest of the time were allowed to go free. In three further experiments the dogs were confined during the inhalation—given once daily, with a very small amount of sputa, a teaspoonful in three days—in a roughly planked box of 12 cubic metres contents, in which, through numerous gaps in the walls, the air could pass in and out. As animals for experiment, dogs were exclusively selected, because they, according to Professor Bollinger, are only with exceeding rarity attacked with tuberculosis; in every case they could move freely about the inhalation-room, and, therefore, were not directly subjected to the stream from the atomizer."

Opposite the second point, *b*, we again place the records of Tappeiner's experiments.

Tappeiner (*loc. cit.*, p. 395) says: "The following are the results of the same eleven (experiments) performed according to the above-described methods, with a statement of age, weight of body at the beginning and at the end of the experiment, as also the duration of the latter:

"No. 1. Age, three years; weight at beginning, 6 kilogr., at end of experiment, 5.5 kilogr. Continuance of inhalations, 42 days. Autopsy: Pleural surface and parenchyma of both lungs thickly infiltrated with minute gray, semi-transparent nodules; in the kidneys and the liver, similar nodules in less number; the remaining organs were, at least by macroscopic examination, found uninvolved and normal.

"No. 2. Age, six months; weight at beginning, 8 kilogr., at end of experiment, 7 kilogr. Duration, 45 days. Same result as in previous case, only the nodules larger, confluent, less transparent, more yellowish.

"No. 3. Age, four years; weight at beginning, 20 kilogr.; duration of inhalations, 24 days; no loss of body-weight. Autopsy: Both lungs, as in previous cases, full of nodules, also visible discreet nodules in the kidneys.

"No. 4. Weight, 5 kilogr.; duration of inhalations, 25 days. Autopsy: Numerous miliary nodules in both lungs."

To these four observations may be added the following, found recorded in Tappeiner's second article—"Neue experimentelle Beiträge zur Inhalationstuberculose der Hunde." (*L. c.*, lxxii, November, 1880.)

Tappeiner (p. 354) says: "For control (of experiments by inhalation of supposed indifferent matter) I allowed at the same time two other dogs, Nos. 1 and 2, in other inhalation-boxes (they were a metre square), to inhale phthisical sputa in the same minimal dose of half a gramme for both dogs."

It may be remarked, by way of explanation, that a half-gramme of phthisical sputa diluted with 100 grammes of water was used for inhalation once daily, fifteen minutes at a time, for ten days; at the end of the inhalation the dog remained in the inhalation-box four hours, and afterward was taken to the common dog-kennels of the veterinary school.

Of the results of these experiments Tappeiner speaks, p. 354 (*l. c.*), as follows: ". . . , while with Nos. 1 and 2 the spleen, as well as both lungs, was studded with numerous gray translucent nodules of the size of a millet-seed. . . . Virchow's second assistant, Dr. Grawitz, pronounced them undoubted true tubercles, both macroscopically and microscopically. . . . Dog No. 1 weighed 13 pounds at the beginning and 11½ pounds at the end. No. 2 weighed 11½ pounds at the beginning and 10½ pounds at the end."

At this time Tappeiner also conducted a series of experiments to discover, if possible, the length of the incubation period—I, *e.*, the time at which the first visible outbreak of tubercle occurs after the beginning of the inhalations. Several examples of loss of body-weight are noted.

The following quotation is introduced, not so much to relate another instance of loss of body-weight after large quantities of phthisical sputa inhaled as to show that not only Tappeiner witnessed the results of his experiments, but often also other trustworthy and experienced men supervised them.

Further, Tappeiner says (p. 358): "At my departure, on August 24th, I left in the dog-kennels of the Pathological Institute dogs Nos. 11 and 12. Both had . . . for fifteen days inhaled large doses of phthisical sputa, and hence must already have been infected with tubercle. One of these was killed by Dr. Grawitz on October 22, 1879, and the note of the autopsy was forwarded to me, on March 3d last, by Professor Virchow. It is in these words:

"Black poodle of Dr. Tappeiner, section Oct. 22, 1879. Small, extremely emaciated, hair almost entirely rubbed off on account of itch, black male poodle-dog. Belly greatly drawn in, covered with yellow adherent scabs.

"Heart firmly contracted, musculature dark-red, firm, valves unaltered.

"Left lung in places slightly adherent to the thoracic wall by a thin layer of fibrin; those places appear cloudy, yellowish-gray upon the surface. The pleura itself is smooth as a mirror; in it quite isolated numerous gray, translucent, miliary nodules are observable, the cut surface of which shows a very large number; at the already mentioned places where the pleura was cloudy a broncho-pneumonic infiltration is found, reaching the size of a walnut. The right

lung is smooth upon the surface; it contains in the pulmonary pleura and in the pulmonary parenchyma numbers of gray miliary nodules; in addition, small areas of flabby hepatization in the dependent portions. The spleen is slightly enlarged, hyperæmic, very dense: follicles small, distinct; no abnormality. The left kidney absent! In its place a stellate scar, and a firm, whitish-gray lymph-gland the size of a hazel-nut. Right kidney correspondingly large, although not altered. Liver large, hyperæmic, in no way abnormal. Intestine almost empty, mucous membrane pale, with abundant epithelial covering, indeed nothing.

"Diagnose: *Tubercula pulmonum et pleurae*.—Pleuritis fibrinosa recens partialis sinistra. Broncho-pneumonia catarrhalis sinistra et pneumonia hypostatica dextra. Hyperplasia lienis chron. Defectus renis sin. Hypertrophia renis dextri. Hyperæmia hepatis."

Thus it is proved that, instead of only "one case" in which Tappeiner observed nodules in other organs besides the lungs, as our author asserts, *no less than five such cases are reported in the two articles referred to*. Furthermore, no less than three of the authors whom Dr. Formad quotes for other purposes have mentioned Tappeiner's experiments as having shown that nodules similar to those in the lungs are of frequent occurrence in the other organs when the duration of the experiment has lasted long enough. The cases quoted above also show that, when the experiments were performed under certain conditions, the animals lost weight and became emaciated instead of "grew fat." The whole series of experiments reported by Tappeiner also show that the greater the amount of sputa inhaled the greater is the tendency to loss of weight. It is true that two or three of Tappeiner's dogs increased in weight, but, as a rule, they were those which had inhaled the sputum in smaller quantity and with less frequency. Yet even these dogs were found to have serious disease of the lungs.

Opposed to the third point, *c*, we submit the following:

The records show that the series of experiments reported in Tappeiner's first article in many cases passed under the eyes of such men as Schweininger and Buhl, and that the series of experiments reported in his second paper were performed in Virchow's Pathological Institute, and under the supervision of such men as Grawitz, Friedländer, and sometimes even Virchow himself. And yet our author seems surprised and bewails himself that "Tappeiner has been so often quoted," and "so much relied upon by Koch and others for the establishment of the mode of the spreading of phthisis." Our author should give some weight to the fact that these experiments also were performed before the commencement of the "bacillary campaign."

Whether or not Tappeiner, Schweininger, Buhl, Friedländer, Grawitz, and Virchow were capable of recognizing a genuine tubercle when they saw it, and were able to distinguish it from a broncho-pneumonic focus, I will not undertake to decide. But when I remember that these men were already renowned pathologists when our author received his medical diploma (which, by the way, was, if I remember rightly, the very year in which Tappeiner began his researches upon inhalation tuberculosis), I confess that,

for myself, I am strongly inclined to prefer their authority, opinion, and testimony as to what they saw.

Indeed, as to the authority of our author, if we are to judge a man by his utterances, it may justly be said that there is ample ground for grave doubt if he possesses really any definite notions as to what a genuine tubercle is or appears to be. Furthermore, what is quoted below in justification of this doubt would seem also at the same time to warrant a suspicion that he is, in addition, still far at sea and greatly befogged in his knowledge of the nature of tuberculosis and pulmonary phthisis, in spite of those "long years of research he has almost exclusively devoted to this subject."

On page 340 of the "Phila. Med. Times," Feb. 9, 1884, left column, par. 8, appears the following language of the author: "No definite understanding concerning a disease can be arrived at unless some fixed conception of the anatomical characters and various expressions of the lesions of that disease is formed. Thus, as regards the question of tuberculosis and pulmonary phthisis, the matter would be much simpler if a general understanding could be arrived at as to the definition of tuberculosis and phthisis in its different anatomical manifestations. *The pivot of the question* is what to call a tubercle or a tubercular lesion." After floundering about in the vain search for "the pivot" among some floating thoughts more or less related to the matter discussed, our author seems at last to give up and in pure desperation grasp at the conclusion that "therefore it is impossible to define tuberculosis either by its anatomical peculiarity or by the pathogenic property of its nodes." (See *l. c.*, next page, par. 4, left column.)

(To be concluded.)

RETRO-PHARYNGEAL ABSCESS.

By JOHN O. ROE, M. D.,
ROCHESTER, N. Y.

(Concluded from page 120.)

A male child, ten months old, had scarlet fever, from which he had apparently recovered two weeks before I saw him.

The course of the fever was mild; there was no marked inflammation about the throat, but there was considerable coryza and conjunctivitis. Shortly afterward the child began to manifest difficulty in swallowing, which gradually increased until he was unable to swallow anything and began to have some difficulty in respiration, and his voice was very much altered.

It was now feared by the attending physician that diphtheria was about to supervene on the scarlet fever, particularly as the fauces appeared red and much swollen, and there was also marked swelling of the neck, externally, on the left side.

I was requested by the attending physician to see the patient with him.

On thorough exploration of the lower pharynx with the finger, this swelling on the left side, which could be plainly seen on inspection, was proved, by its soft, doughy, fluctuating character, to be a retro-pharyngeal abscess, although it had not before been suspected.

Incision of the abscess was at once made in the manner described in the other case, and the child was immediately relieved. He rapidly recovered, and has had no trouble since. Eighteen months have now elapsed.

DIAGNOSIS.—An early diagnosis of this affection is of the utmost importance, for several cases are reported in which death resulted from failure to detect the abscess during life.

Dr. C. Elliott* reports a case in a child, three years old, who died apparently from exhaustion, with marked nerve irritation and spasms. On post-mortem examination, a retro-pharyngeal abscess was discovered.

A case is reported by Gyselyncx,† and another by Gibney,‡ in which the abscess was only discovered after death. Cases are also reported where the abscess was not discovered until after the children had ceased breathing, but, on opening the abscess immediately and employing artificial respiration, they recovered. Such cases are reported by Smith,* Cayley,|| and Sands.△

The two means of diagnosis on which we should solely rely in making an examination for retro-pharyngeal abscess are inspection and palpation. The former is sufficient in those cases where the swelling is located in the central portion of the pharynx, but those located high up or low down can not be seen. Thus, in the case referred to, reported by Elliott,◇ repeated inspections of the throat were made, but the abscess, which was found on post-mortem examination located high up, was undetected. Also, in the one reported by Gibney,‡ the abscess was so low down that it could not be seen during life.

Inspection of the pharynx in young children is in many instances no easy task. In the case of a struggling child with its narrow pharynx, which is usually filled with mucus, and often with eructations of milk caused by the gagging induced by the presence of the tongue depressor, the examination is generally very unsatisfactory in its results.

Palpation with the finger is, therefore, not only indispensable in diagnosing retro-pharyngeal abscess, but is, in fact, the only reliable means of arriving at a correct diagnosis.

In those cases where a swelling is suspected but can not be seen, the finger is indispensable to discover its location; and, when it can be seen, the finger is also indispensable to determine its true nature—whether it is fluctuating and contains pus, or whether it is an aneurysmal tumor palpitating synchronously with the heart; and to differentiate an abscess from fibrous, osseous, or other tumors which may occupy the pharynx.

On suspecting an abscess that can not be seen, the vault as well as the lowest portion of the pharynx should be thoroughly explored with the finger. To facilitate a more thorough examination of the fauces, especially in obscure cases, Giralde's‡ has recommended the employment of chloroform, a procedure which Schmitz‡ condemns. He says: "Never

‡ (*op. cit.*)

would I think of chloroforming a child for the purpose of making a thorough examination, as recommended by Giraldès."

Bókai, in describing his method of making a thorough examination, and, in cases of diphtheria, of protecting his finger by keeping the child's jaws apart with Ulrich's oral speculum, or, in its absence, a spoon-handle or piece of wood wrapped with cloth, says: "I have never failed in making an examination, nor has it ever entered my mind to follow Giraldès's peculiar advice to use chloroform. I hope," he says, "that this advice will also not be followed by others."

Pauly,* on the contrary, says that he does not agree with Schmitz and Bókai as to the danger of the use of chloroform, for the reasons that,

1. The danger of suffocation is not increased by the use of chloroform, as illustrated in operations of tracheotomy for croup.

2. The exploration can be made more thoroughly, and the operation can be done by inverting the child while under chloroform, or hanging it down over the edge of the table, as proposed by Rose and Wolf.

Judging from the relief which I have seen chloroform give in cases of laryngeal obstruction from different causes, I am inclined to agree with Pauly that the use of chloroform is advisable in obscure cases where a thorough exploration is necessary, and for the purpose of quieting an ugly child to facilitate the operation of opening the abscess. As so little chloroform is required, the only real danger is in the escape of pus into the larynx, which can be readily prevented by depressing the head.

COMPLICATIONS.—Among the dangers that may arise to complicate this affection and to threaten the life of the patient, the principal one to be guarded against is suffocation, either from rupture of the abscess and the sucking of pus into the larynx, from closure of the larynx by the direct pressure of the swelling, or from secondary œdema of the glottis.

Rupture of the abscess spontaneously in a child during sleep is almost invariably fatal from suffocation.

Justi† refers to several such cases of suffocation in bed from rupture of the abscess, reported by Opolzer in his lectures edited by Stoffella.

In other instances of spontaneous rupture of the abscess the quantity of pus may be so great as to suffocate the patient, as in the case reported by Gaupp.‡

Edema of the glottis is by no means of infrequent occurrence in fatal cases of retro-pharyngeal abscess, as the result of burrowing of pus into the ary-epiglottic folds. Schmitz § reports the occurrence in a child six months old. Laryngeal œdema in adults is also a frequent and serious occurrence in cases of retro-pharyngeal abscess, and also as accompanying abscesses occurring in the other visceral spaces of the neck.

Dr. Lidell* has, in his very excellent article, collected from various sources ten different cases of abscess in the cervical region in adults, three of which were retro-pharyngeal.

One is reported by Dr. Levestin,† occurring in a peasant aged forty-six. The abscess followed typhus and gastric fever. Dyspnoea became urgent, and tracheotomy was performed, notwithstanding which he died two days later from asphyxia. The autopsy revealed an abscess behind the lower portion of the pharynx.

Convulsions are a complication that frequently arises, as seen in the cases reported by Elliott, Bókai, and Schmitz.

Bókai has also observed facial paralysis in four cases.

Death from hæmorrhage, from opening of the carotid or its branches after the opening of the abscess, seems to be a not very infrequent complication.

Dr. Carmichael‡ reports a case of a child, five weeks old, in which pharyngeal abscess was diagnosed but not opened. Next day the child died suddenly from hæmorrhage from rupture of both the abscess and the carotid. A post-mortem showed the abscess to be the cause of the softening of the coats of the artery.

Similar cases are also reported. Thus,

Gautier § reports two cases of sudden death from hæmorrhage.

Bókai|| reports a case of a child, four years old, that died from the abscess opening the carotid.

Lidell cites the case of a young man,^Δ aged fifteen years, who had a swelling in the back of his throat and the sides of his neck, which was not opened. Sixteen days afterward hæmorrhage occurred from his mouth and nose, and two days later an abscess opened spontaneously in his throat. On the second and fourth day after there was more hæmorrhage. During the fourth week the abscess burst a second time, and the patient soon died suddenly from hæmorrhage. The post-mortem showed caries of the anterior surface of the body of the atlas, and an abscess cavity located between the right tonsil and parotid gland, involving branches of the carotid.

In this case it was considered that the caries was the cause of the abscess, but to my mind it was just as certainly the result of the erosive action of the pent-up pus as the giving way of the arterial vessels was. In fact, I am quite of the opinion that, in some of the cases where disease of the vertebrae is found in connection with an abscess that has remained unopened for any considerable length of time, either in adults or children, the disease of the vertebrae is much more likely to be the result rather than the cause of the abscess, as is the case with the giving way of the resisting coats of the arteries.

§ "Dis. of the Throat and Nose," Lond., 1890, vol. i, p. 21.

Op. cit.

Dr. Cohen* cites a case reported by Reeves† which clearly confirms this statement. At the time of death an abscess was in the course of production. Examination showed the periosteum and common anterior ligament gone in parts, and the bone exposed and eroded in patches—evidently the result of the pressure of the abscess, inasmuch as the bones were not carious and the joints were intact.

TREATMENT.—In all cases where pus can be detected it should be immediately evacuated. From a study of fatal cases of retro-pharyngeal abscess, it is seen that in the majority of them death resulted either from failure to suspect the abscess and seek for it, or from failure to find the abscess when suspected, as is shown in several cases cited; or from failure to open the abscess promptly when detected, thereby preventing the occurrence of suffocation; or from the burrowing of the pus into the deeper tissues, which may occasion the softening or ulceration of the coats of important blood-vessels and other tissues.

From this failure to timely detect and to open the abscess unquestionably many lives of children, and of adults also, have been sacrificed that might have been saved. Henoch‡ cites a case in which a colleague, who wished to keep the patient in question until the next day for clinical demonstration, paid for the delay by the sudden death of the child during the night from suffocation.

The method of opening the abscess and the location of the incision depend on the seat of the abscess. If it points or is found bulging into the pharynx, a free incision into its most dependent portion is necessary only. If there is marked swelling of the side of the neck, with the formation of pus, external incision is often also necessary. In sixteen cases reported by Schmitz, three were opened externally and five both externally and internally. Bókai reports two cases that were opened both externally and internally.

Various methods have been from time to time proposed for opening the abscess, as the trocar and cannula, the aspirator, the guarded bistoury, and the finger-nail. The use of the aspirator and trocar was suggested to prevent the escape of pus into the larynx. Care should, however, be exercised in their use lest injury be done the vertebrae.

Albert* adopts the plan of making a very small incision at first, to allow the pus to escape slowly and not suffocate the child, and afterward enlarges the incision.

Justi employs a retro-pharyngotome of his own device, which is figured in his article.

Schmitz has devised a knife with a concealed blade which can be thrown out when it is *in situ* against the wall of the abscess. By it danger of wounding other parts is avoided when the child persists in struggling. Before devising this knife, Schmitz on one occasion attempted to open an abscess with a bistoury, when the tongue of the child slipped from under his finger and the knife was plunged into the tongue. Hemorrhage was so copious that the blood was sucked into the larynx and the child became asphyxiated.

It was, however, resuscitated by introducing a female catheter into the larynx and employing artificial respiration.

In opening deep-seated abscesses, Steffen* recommends counter-pressure on the corresponding side of the neck with one hand while the index-finger of the other is passed in deeply behind the larynx.

Chiene has proposed that in every case of retro-pharyngeal abscess the opening be made externally, and (although Dr. George McClellan,† of Philadelphia, had used antiseptic dressings prior to 1848 in the treatment of cervical abscesses after they had been opened) he is the first to propose that the opening be done antiseptically after the method of Lister, which he describes in a communication to Duprés,‡

In eleven out of seventeen cases Schmitz found a fluctuating swelling behind the angle of the lower jaw (usually on the right side), and, on opening this, a direct communication could be shown between it and the pharyngeal abscess.

This same fact is shown in some of Bókai's cases.

In some of Schmitz's cases, where both an external and an internal incision were made, fluids and a probe could be passed from one opening to the other.

This clinical fact corresponds entirely with the known anatomical connection between the retro-visceral and lateral visceral spaces of the neck, and would render it eminently advisable to open the abscess externally in all cases where it tends to point externally, and where the pus tends to burrow and the deeper structures threaten to become involved.

This is advisable because—

1. Thorough drainage can be maintained and no secondary operations are required.

2. The pharyngeal wound is avoided in which foreign and irritating substances can lodge or sacs or pockets form, which has been complained of by some authors.

3. In cases of necrosis of the vertebrae, the opening of the abscess antiseptically and the use of antiseptic cleansing injections give the patient the best chance for recovery. In some cases, however, it is advisable to make both an internal and an external incision for the purpose of thorough drainage where the drainage by the external incision alone is insufficient.

Chiene reports a case of caries of the cervical vertebrae which he cured by adopting this antiseptic method.

In opening the abscess externally, the incision should be made along the posterior border of the sterno-cleido-mastoid to avoid the large vessels.

The cut is usually made with a knife, but those who have employed the director and dressing-forceps, as recommended by Hilton, in opening deep abscesses where important vessels are in danger of being wounded, will never attempt it by any other method. Those who have never adopted it should not fail to read Hilton* on the subject.

Hilton's method of opening deep abscesses about the neck and elsewhere is as follows: An incision is first made through the skin. Then a blunt-pointed grooved director is pushed into the swelling down to the pus. Then a pair

of small dressing-forceps, with the blades closed, is forced along the groove down to the abscess, and, by partly opening the blades on withdrawing the forceps, a free opening is made.

Hilton reports a case of retro-pharyngeal abscess which he opened externally, and which he considered unsafe to open in any other manner. In this case there was caries of the cervical vertebræ which resulted in complete recovery.

In all cases more or less attention should be given to the general constitutional condition.

In adults the treatment required will depend on the cause or the disease of which the pharyngeal abscess is a complication.

In children there is usually added a scrofulous dyscrasia, which should be removed by appropriate anti-strumous remedies, and all known means at command should be employed to promote the invigoration of the child.

DISCUSSION.

Dr. DE BLOIS.—I have been very much interested in Dr. Roe's paper, embodying as it does the results of much laborious research, particularly as I myself have had three cases, one of which was in an adult and the two others in children. In one of them the incision had to be carried through the posterior pillar of the fauces. I differ with Dr. Roe as to making the incision a small one, and believe that it should be free and the pus be evacuated at once, but that after the incision the head should be forced down. If the patient is a child, it should be turned upside down. I think the position in which the head is carried—that is, very far backward—should be taken into account.

Dr. JOHNSON wished to call special attention to the horizontal incision and inversion of the patient—that appearing to be the most satisfactory method of evacuating the abscess.

Dr. JARVIS.—I think more stress should be laid upon the occasional occurrence of retro-pharyngeal abscess in connection with ordinary tonsillitis. A case of this kind has come under my observation in which the condition existed, along with acute suppurative of the tonsil, resulting in strangulation of the patient.

Dr. LEFFERTS.—The paper of my friend illustrates very well the relative value of theory and practice; its bibliographical research is large, but too speculative and theoretical in its results; no practical deduction can be drawn from it. His clinical cases, on the other hand, are plain and to the point. He tells what he has seen and done. One clinical fact well observed is worth pages of theory. Take, first, the matter of causation. Who in this audience of experts believes that nasal catarrh in children is ever a cause of retro-pharyngeal abscess? If it is so, why do we not see the latter oftener? Who believes that tuberculosis of the pharynx is ever a reason? Tuberculosis of the pharynx is the rarest of diseases; some deny that it ever occurs. Who has ever seen an injury to the posterior pharyngeal wall followed by abscess? And yet all these causes have been given us in good faith. Retro-pharyngeal abscess, aside from that form arising from caries of the cervical vertebræ, which must be rare, is probably due to a simple phlegmonous inflammation of the cellular tissues in front of the spinal column, arising from causes which produce similar abscesses elsewhere, and the reason of these is not always demonstrable. Take the matter of diagnosis. It seems to me that there is little value in speculating whether the patient's head is held forward or backward, whether inspiration or expiration is most affected, and the like variety of symptoms that have been given us. One look into the patient's throat is enough. Few conditions can be con-

founded with retro-pharyngeal abscess; a suppurating gumma is one. In treatment, again, why not sum the matter up in one word, by saying that a retro-pharyngeal abscess must be treated upon the same surgical principles as an abscess elsewhere in the body—open it and discharge its contents? I care not if the incision be transverse, or if it be made from below upward, or from above downward—all of which matters have been dwelt upon.

Retro-pharyngeal abscess must be rare. In literature how comparatively few examples are met with in comparison with all the cases detailed! Personally, I have seen but two examples, both in young children; both patients were operated upon by simple incision; there was no difficulty in the diagnosis; and both recovered.

Dr. COHEN remarked that the danger of suffocating the patient on incision of the abscess might be avoided by operating with the head pendent. As to the horizontal incision, recommended by one of the speakers, he believed that the danger of leaving a pocket in the lower portion of the abscess, in which pus might accumulate, had been mentioned by some authors as a reason for preferring the vertical incision.

Dr. DONALDSON stated that he had had but one case of retro-pharyngeal abscess, in a child three years of age. The tumor was so large as to fill up the naso-pharynx and extend down into the lower pharynx, pressing upon the epiglottis and thus causing considerable dyspnoea. Fluctuation was evident, and the diagnosis was easily made. In view of the danger of the pus flowing into the larynx from an incision with a bistoury, he selected a point situated high up, where the wall of the abscess was not very thin, and, introducing a fine aspirator-needle, drew off about an ounce of pus. After this he made a free incision, and the child was completely relieved. He thought the aspirator the best and safest means for emptying retro-pharyngeal abscesses.

Dr. GEORGE W. MAJOR stated that his experience of retro-pharyngeal abscess corresponded in the main with that of the fellows who had already spoken. There occurred to him at the moment three cases having a bearing on the present subject—two cases of abscess proper, and one that had been referred to as an abscess. The first case occurred in a child, aged four years, as a sequel of measles. The difficulty of breathing and swallowing was very great indeed, but was immediately relieved on incision and evacuation of the pus. The second case followed after cerebro-spinal meningitis. Swallowing, even of liquids, was almost impossible, and breathing dangerously embarrassed. On making an opening, immediate relief followed. The third case had been referred to him as one of abscess by an ophthalmic surgeon, whose clinic the patient was attending for a neuralgia and prominence of the left eye, from which no relief was had. Although palpation did not detect the presence of pus, and an exploratory incision revealed a growth evidently malignant, eighteen months subsequently, at the post-mortem, a large sarcoma was found to have caused absorption of a large portion of the base of the skull, and to have been pressing on the brain. The last case was referred to as showing the possibility of making an error in diagnosis in such cases.

Dr. LINCOLN.—To illustrate the fact that other operative interference than a simple incision in the posterior wall of the pharynx is sometimes necessary in order to get rid of the contents of these abscesses, I will refer to a case I was once summoned to see, in which the patient, a child three years old, was supposed to be dying. It had been under the care of a homœopathic physician, who had failed to recognize the true nature of the disease. The prominence of the abscess not only filled the back of the mouth, so as to stretch the soft palate, but caused a bulging on each side of the neck, under the angle of the jaw.

On incising the abscess in the pharynx, this part immediately collapsed, affording prompt relief from the threatened suffocation; but there was no perceptible change in the size of the swellings in the neck, although they seemed to be less tense. By introducing an aspirator-needle into each, they were readily evacuated, but on the left side it was necessary to repeat the operation twice.

Dr. MACKENZIE called attention to the possibility of confounding a gummy syphilitic tumor of the posterior pharyngeal wall with a retro-pharyngeal abscess, and related a case referred to him in which the mistake had been made by a brother practitioner.

Dr. E. FLETCHER INGALS was surprised that in the experience of others retro-pharyngeal abscess was so rare, though it had been rare in his own experience, which embraced but two cases. One of the patients was a child, about ten months of age, who had an abscess mostly above the palate, which had opened a few hours before he saw it. It was supposed to be due to the youthful indiscretion of its father. The second case was in a man, about fifty years of age, who came to him because of laryngeal trouble. The day he presented himself he had coughed out what had the appearance of being about one half of the ossified cricoid cartilage, the site of which was clearly seen upon laryngoscopic examination. About three weeks later a retro-pharyngeal abscess was developed, which progressed slowly, and finally opened spontaneously. About four weeks afterward he had been called to see the patient for symptoms which appeared to be those of cerebral disease. Owing to other engagements, he did not see the patient, but saw by the papers a day or two afterward that he had died of some cerebral disease. The cause of the retro-pharyngeal abscess seemed to have been the same as that of the meningitis which finally caused the man's death.

Dr. CHAMBERLAIN.—Two cases of retro-pharyngeal abscess have been under my observation. The first was during an epidemic of cerebro-spinal meningitis in Hartford, occurring in a child of about eight years. The abscess was situated behind the palate, and followed the usual course, healing after incision. The second case was apparently unique; at least I have seen no similar case recorded. The abscess was situated posteriorly to the left tonsil. As the case occurred in the country, its importance was not at first recognized. When urgent symptoms set in, I was sent for, but arrived too late. When the abscess opened spontaneously, very profuse hemorrhage followed, and death ensued almost immediately. Post-mortem examination showed that the cause of death was rupture of the internal carotid artery, from weakening of its walls by the abscess. It was extremely probable that the child had inherited some taint from the father, whose habits before marriage had not been above suspicion.

Dr. ROE, in closing the discussion, said, in reply to Dr. Leferts, that his only object in dealing with the theoretical points had been to direct attention to the conditions which might cause post-pharyngeal abscess, when the indications regarding diagnosis and treatment would be plain. But in many cases the symptoms were so obscure that, unless we took into consideration all the possible conditions, the true one might be overlooked. With regard to the rare complications, for instance that of necrosis of the vertebrae, he believed they might be avoided by early recognizing the disease and resorting to proper treatment. As to the occurrence of retro-pharyngeal abscess in children as a result of nasal catarrh, he coincided with the views of Broca, Jacobi, and others, that in many of the cases of post-pharyngeal abscess following diphtheria, scarlet fever, etc., in children, the patients suffered from the "snuffles," and the relation of the lymphatic channels in the region of the naso-pharynx to those

in the pharynx proper was such as to justify the opinion that inflammation affecting the former had led to inflammation and ulceration of the latter.

REMARKS ON GYNÆCOLOGICAL THERAPEUTICS.*

By J. H. EMERSON, M.D.,

PHYSICIAN FOR DISEASES OF WOMEN TO THE OUT-PATIENT DEPARTMENT OF
THE NEW YORK HOSPITAL.

I PROPOSE to run over very briefly the principal therapeutic agencies that I employ in my clinique at the New York Hospital, Out-Patient Department, stating what I conceive to be the indications for their use and the objects aimed at, and, so far as I can, the results believed to have been attained. Unfortunately, it will not be possible to formulate these with precision, the same remedies finding an appropriate use in numerous classes of cases, various affections existing in multiform combinations, and very many of the cases being chronic, and a good number curable by surgical procedures only, which are often of necessity almost indefinitely postponed. Still, I hope it may not be unprofitable to make such a review, for the sum of professional opinion regarding matters of every-day treatment is not made up from laboratory experiments in nearly so great a degree as from the observations of individuals, and even such humble contributions as this may modify or strengthen the views of my hearers, or, as I certainly hope, may elicit discussion and criticism here.

I use pessaries, chiefly the Albert Smith, the Thomas bulb, and the elastic ring; these for backward displacements; and as such are in my experience much more frequent than anteversions and antelexions, I have much less occasion to employ instruments for the relief of the latter. For cases of prolapse with a heavy uterus and a damaged perineum, I believe that such instruments only as have an external support would be of any value. Simple abdominal belts or supporters will often obviate the need of pessaries, especially in anterior displacements. I can not enter more fully into this topic.

Cutting operations of any importance, and even curetting, are inadmissible in patients who have to return on foot to their homes immediately after treatment, and therefore are not referred to at this time.

In regard to the hot douche, it is ordered in almost all cases as a matter of routine, and I find that in the class of patients I see at this institution there are few who can not afford a bed-pan. I therefore give explicit directions to them to use the syringe in connection with this article and in the recumbent position, using two or three quarts of water, as hot as it can be borne. I always try to make sure that the nozzle does not have a terminal orifice, and, in cases of patulous os uteri, or where complaint is made of pain after using the douche, I advise the bent and partly flexible nozzle devised by Dr. F. P. Foster.

Ergot is used in gynecological practice chiefly with three objects: one is to effect a reduction in the size of the uterus by promoting the contraction of its muscular elements and reducing the caliber of its blood-vessels, another

* Read before the New York Clinical Society, April 25, 1884.

is to check uterine hæmorrhage, and a third is in the treatment of interstitial and submucous fibroids. I would say that for nearly two years past I have employed the preparation of ergot made by Parke, Davis & Co., under the name of "*Liquor ergotæ purificatus*," and which I first tried on the recommendation of Dr. T. A. Emmet, who found it less nauseous and commonly better borne by the stomach than the fluid extract of the pharmacopœia. I have seen no reason to doubt its efficiency, and have met with few complaints of difficulty in taking it. Ergot when given with the first object has been eminently unsatisfactory. The cases in which I have used it have been mainly those of subinvolution, often associated with a greater or less degree of laceration of the cervix. In combination with the ergot, the local treatment has usually aimed at an unloading of the vessels of the uterus by the action of glycerin tampons and stimulating the blood-vessels to contract by the hot douche. Even after the use of the drug had been continued in some instances for many weeks, repeated measurements with the sound showed little or no decrease in the length of the organ, although the general symptoms of the patient and the appearance of the vaginal portion of the uterus indicated improvement. Patients with subinvolution, thus associated with and doubtless referable to lacerations of the cervix, are not apt to present themselves at the hospital until months after the confinement at which the injury was received—after a period, namely, during which the hæmorrhages, the leucorrhœa, the displacements, or other results of the original lesion have been developed, and have become the incentives which brought the patient for treatment. By this time the reconstructive impulse in the uterine fibers which exists after delivery and effects the involution of the organ has well nigh ceased, and the fibers no longer respond to the stimulus of ergot, to which they were so sensitive at an earlier period. I can hardly say that I have proof of the value of ergot given simply to arrest uterine hæmorrhage, although there are many cases in which I should feel that I was not right in withholding it. Still, in these same cases other measures, such as the hot douche and swabbing the uterine canal with tincture of iodine, are likewise resorted to—the effects of which are more palpable—so that one remains uncertain what the share of the ergot has been when the flow is checked. Few cases have presented themselves where the third use of ergot could be observed. The greater number of such probably find their way into hospital wards, and I have nothing to report in this connection.

There are cases of prolapsus uteri in the third degree, notably among washerwomen, or others leading laborious lives, who have to stand much and lift heavy weights. Many such have doubtless had their origin in a laceration of the perinæum, complicated probably with a subinvolved uterus, and when they apply for treatment can not afford the time required for operation, even though, in the case of some, nothing short of a closing of the vaginal orifice would secure them from a recurrence of the prolapse. Such patients have been benefited by the frequent introduction of cotton tampons saturated with the glycerite of tannin, and by a douche of cold water, to which I have sometimes added a few drops of the persulphate or perchloride of iron.

This may lead to the subject of iron. In a practice where no cutting operations can be performed, the need of those preparations of iron which are used locally as direct hæmostatics does not exist. I believe the tincture of the chloride of iron has a decided value in checking metrorrhagia, when given only on such occasions, but I also believe that the continued use of large doses of this drug by women who are liable to excessive flowing tends to aggravate rather than relieve the difficulty. This may be due in part to its constipating action, although this can generally be obviated by combining with it the tincture of nuxvomica. When anæmia is the most prominent feature, I rely chiefly upon Blaud's pills, finding them easily administered and assimilated, and less likely than some other preparations to occasion constipation or headache.

In that very common group of symptoms, viz., backache, constipation, leucorrhœa, "general debility," and moderate pelvic inflammation, I derive the most satisfactory results from the well-known combination of the sulphates of iron and magnesium with sulphuric acid, and perhaps a bitter infusion, given largely diluted. This is, of course, supplemented by the hot douche and by glycerin tampons.

It is almost needless to say that a very large number of cases receives hardly any other treatment than the hot douche, local applications of Churchill's tincture of iodine, supplemented by the glycerin tampon, and the exhibition of cathartics, preferably the salines, or those containing senna. I commonly use the mixture of sulphates mentioned just now, the compound licorice powder, or an infusion of senna, quassia, anise, and bitartrate of potassium, which latter serves a good purpose in relieving the flatulent dyspepsia which is so frequent an accompaniment of these affections. A measure on which I place no little reliance when the cervix is found engorged, firm, and dark, is scarification, repeated every few days; and under its use, even though the amount of blood drawn be but a few drachms, I have seen cervical catarrh diminish, erosions heal, and the vaginal portion of the uterus recover its natural consistence and tint.

I have not learned how to use either cannabis indica or hamamelis for the relief of uterine hæmorrhage, although I have made some trial of both; but gallic acid I find efficient for this purpose, and usually give it in doses of ten or twenty grains, dissolved in alcohol, to be taken in a wine-glass of water.

Ovaries, whether displaced or not, are often sensitive and painful enough for that symptom to demand special attention, and I have employed various sedatives, both by themselves and more commonly in connection with derivatives and counter-irritants. Thus, I have used blisters externally, as well as tincture of iodine; also tincture of iodine by itself and mixed with tincture of aconite root, painted upon the vaginal mucous membrane, as near as may be to the sensitive organ; belladonna by the mouth and applied *per vaginam* in an ointment with iodoform, as also the fluid extract of eucalyptus; bromide of potassium also by the mouth. I conclude that little direct relief to pain comes from any of these sedatives as applied *per vaginam*, any apparent good being more properly referable to the support

furnished by the cotton tampon, and to the derivative action of the glycerin with which it is often impregnated. Undoubted and prompt relief has been seen to follow a blister, and more gradually the painting of tincture of iodine over the painful region in the groin. It has appeared to me that something has been gained by the persistent administration of bromides and belladonna.

It is easy to satisfy one's self of the deodorizing, and presumably of the antiseptic, properties of the eucalyptus, even if it does not now maintain its reputation as an anodyne.

Here I may refer to two articles which have done good service in relieving the pain of dysmenorrhœa, viz., small doses of chloroform given by the mouth, according to an old formula, with camphor and peppermint water, and, secondly, chloral given as an enema.

As antipruritics, and to dull the sensibility at the orifice of the vagina in the slighter degrees of vaginismus, nothing has been so satisfactory as carbolic acid penciled on, or a 1-to-1,000 solution of bichloride of mercury. This latter salt, in a weaker solution, has proved most serviceable also in some cases of obstinate vaginal leucorrhœa, presumably of gonorrhœal origin. The infection appears to lurk in the follicles of the mucous membrane, especially of the fornix vaginæ, a region which ordinary douching and modes of dressing fail to act upon so effectively as upon the lower and more accessible portions of that canal, partly, no doubt, because there is here less distension of the mucous membrane, the deeper recesses of the folds thus escaping the action of the medicaments employed.

Finally, I may mention two drugs which, in my experience, have not deserved the reputation claimed for them by some recent writers. These are viburnum, as a uterine sedative, and apiol, as an emmenagogue.

A CASE OF HYPERTROPHY OF THE MUCOUS GLANDS OF THE LIPS.

By J. WILLISTON WRIGHT, M. D.,

PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY
OF THE CITY OF NEW YORK; SURGEON TO BELLEVUE HOSPITAL.

FRANK W., aged eighteen, a native of the United States and a jeweler by trade, presented himself at the college clinic, December 7, 1881, on account of the unsightly appearance of his mouth, which he thought had existed ever since he could remember.

On examination, the mouth was found to be abnormally large, and, as the teeth were prominent and very irregularly placed in the jaws, the expression of his face when the mouth was opened, as in the act of laughing, was simply frightful. (See Fig. 1.)

The upper lip was disfigured by its unusual thickness and by the presence of two pendulous and everted folds of tissue covered by mucous membrane, one on either side of the middle line, projecting from the inside of the mouth, so as to form a double lip, each fold being somewhat thicker than the natural lip above it. The under lip was the seat of a similar eversion, consisting, however, of a single fold, but extending from one angle of the mouth to the other. (See Fig. 2.)

Both lips were dry, rough, and deeply fissured in many places.

On pinching these everted folds between the thumb and

finger, numerous small, more or less movable, bodies, the size of hemp-seed, could be distinctly felt. The patient stated that

FIG. 1.

the condition was not only a source of great inconvenience, owing to the irritation induced by the constant recurrence of fissures or cracks, but that it was made the subject of frequent and humiliating remark among his acquaintances, to such an

FIG. 2.

extent, indeed, that he was debarred from all social enjoyment, and that for several years past he had been in a reckless, despondent, and unhappy frame of mind, caring little what became of himself, and often seriously contemplating suicide.

The diagnosis of hypertrophy of the mucous glands of the lips having been made, the patient was advised to subject himself to an operation for their removal, a proposition which he accepted with positive enthusiasm, saying he would gladly sub-

mit to any number of operations which offered the slightest probability of improving the appearance of his mouth.

Operation.—A strong silk ligature was passed through the outer portion of the upper lip, just above the angle of the mouth on either side, and given into the hands of an assistant in order to thoroughly evert the lip and hold it in that position.

Two elliptical pieces of mucons membrane, extending from the frænum to the angle of the mouth and measuring half an inch in width at the widest part, were then dissected from either side of the inner surface of the upper lip and removed. Next the enlarged mucous glands, together with the thickened connective tissue in which they were imbedded, were snipped from the bottom of the wounds with curved scissors.

Both coronary arteries were freely exposed, but were easily recognized and avoided.

The wounds were then accurately closed with numerous fine points of interrupted suture, composed of a single strand of horse-hair.

The lower lip was treated in a similar manner, with the exception that a single semi-lunar-shaped piece of mucons membrane, with its convexity looking upward, was removed instead of two elliptical portions. This piece extended from one corner of the mouth to the other, and, like those of the upper lip, was something more than half an inch in width at its middle or widest part.

The wounds healed throughout by the first intention, one of the sutures being removed on the third day after the operation, though both lips remained somewhat swollen for about ten days. The patient was subsequently placed in the hands of a competent dentist, under whose skillful management his teeth were straightened and otherwise greatly improved in appearance.

April 26, 1882.—The lower lip is now perfectly smooth, all of the fissures having healed under the use of the dilute ointment of nitrate of mercury; it is normally thin, free from eversion, and of a satisfactory shape. The whole mouth is much smaller than before the operation, but the upper lip is still somewhat thicker than desirable, with a slight remaining tendency to eversion.

FIG. 3.

Patient etherized, and another thin strip of mucous membrane removed from the inside of the upper lip as before.

Union by first intention, and patient discharged at the end of a week.

Fig. 3 is from a photograph taken two months after the last operation.

April 25, 1884.—Saw the patient to-day and examined the mouth.

The lips are moderately thin, well shaped, and showing no tendency to eversion; they are perfectly smooth, free from cracks, and the scars resulting from the operations are almost imperceptible.

The moral effect of the operation has been even greater than the change in his physical appearance, though secondary to it, and is, therefore, the most interesting and satisfactory part of the history.

By removing from a conspicuous locality an unsightly deformity, it has apparently changed the whole current of the man's life, and, while giving him an infinitely better-looking face, has also developed a higher sense of self-respect, together with a largely increased capacity for social enjoyment.

THE SURGEON'S POCKET-CASE.

By FRANZ HEUEL, JR., M. D.,

SURGEON TO THE CITY HOSPITALS ON RANDALL'S ISLAND; PROSECTOR TO THE CHAIR OF SURGERY, AND INSTRUCTOR IN OPERATIVE SURGERY, AT THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

In the following description I wish to call attention to an improved pocket-case of instruments which I have used for some time, and which I have found of great utility. It was made for me by Messrs. George Tiemann & Co., of this city.

The average pocket-cases, as furnished by instrument-makers for the surgeon's use, are either too small, being mere dressing-cases, or too large and clumsy to be conveniently carried. In the former case the instruments are too few in number and too small to be practically useful; in the latter, containing many which are obsolete or have been supplanted by newer and better models. My idea of a surgeon's pocket-case is that it should be made of the best materials, contain the best of instruments and those of the most approved design, be a minor operating-case, and, in emergencies, be suitable for even the larger operations, at the same time not too large to be conveniently portable.

My case, which I usually carry in a chamois-lined hip-pocket, is five inches and a half long by three inches and a quarter wide, and one inch in thickness. It is made of alligator, seal-skin, or morocco leather, the latter being the cheapest and thinnest, while it is also very durable. It

is lined with the best silk velvet, is four-folding, with retaining flaps (see *a* in accompanying figure), and has no

pockets, these being liable to tear. In opening, it appears like a two-fold case, having the thicker instruments as close together as possible, though not crowded on one another. Each flap (*b, b*) may then be opened, revealing (*c, c*) on one side the thinner instruments—such as probes, blunt dissectors, etc.—and on the other the needles, pins, etc., neatly arranged in rows upon the flap in the best of thick flannel (this not rusting them as chamois-leather would do if the case was dampened by perspiration), together with a variety of plaited and black iron-dyed silk, horse-hair, and catgut sutures, ligatures, thin isinglass plasters, etc.

The instruments consist of, firstly,

Knives.—These are two in number, and, like the one shown in the accompanying cut, are four-bladed, having spring catches and tortoise-shell handles.

The first contains a large and a medium-sized scalpel on one side, a blunt curved bistoury and Syme's abscess knife on the other.

The second contains a small tenotome and small bistoury, a Graefe's linear cataract knife, and a half-curved canalicula knife. The gum lancet has been omitted from the case, since either of the scalpels, or the tenotome, will meet all of its requirements. The various-sized scalpels will answer for amputations, even up to the shoulder joint, removal of tumors, etc. Syme's abscess knife I prefer to the common, thick-backed, curved bistoury, as it is double-edged, and hence gives less pain in its introduction. Graefe's linear knife is very useful for amputating the fingers in children, while the half-curved canalicula knife is well adapted for opening styas, and for other delicate work.

Secondly, *Scissors.*—These have closed rings, which are preferable to those with open handles, as they are much steadier in the fingers. They are slightly curved on the flat, thus answering the purpose of both curved and straight scissors, which is a great desideratum in some cases, having one dull point for removing dressings without injuring the skin, and one sharp point to easily and painlessly cut sutures. They also have a French joint to admit of more thorough cleauing.

Thirdly, *Forceps.*—These are six in number, five of

which can be used for controlling hæmorrhage in case of necessity:

No. 1 is useful as a fixation, torsion, dressing, and dissecting forceps; it has an Esmarch's slide-catch, which is removable, so that the forceps may be thoroughly cleaned.

No. 2 is an Andrew's artery forceps with Esmarch's slide.

No. 3 is a combined polypus, dressing, and artery forceps, with ring handles, ratchet clamp, French joint, and longer jaws than those shown in cut.

No. 4 is a Piffard's grappling forceps with Esmarch's slide-catch. This I have found a very useful instrument in removing tumors, cysts, bullets, and foreign bodies.

No. 5 is a needle forceps of my own design, with duck-bill jaws and a Russian catch, *a*.

It will hold with equal firmness a fine needle or a coarse instrument, giving a secure hold for the hand, and is very useful in removing splinters, needles, toe-nails, etc.

No. 6 is a small-sized, strong bone-cutting forceps, made after Liston's pattern, and having a reversible spring, *a*. The

cut shows the instrument ready for use; when in the case, the spring *a* is reversed to prevent spreading of the handles. It is very useful in operating about small bones like those of the hand, for cutting pins, wire, etc., and can be employed in a very small space.

Miscellaneous instruments:

The *Thermometer* is self-registering, well seasoned, and

placed in a thin coin-silver case having cotton in both ends to avoid breakage.

The *Hypodermic Syringe* has a graduated glass barrel with a fenestrated metal guard, and graduated piston-rod with screw adjustment, *b*.

Nested in the piston-rod are one coarse and one fine needle confined by a screw-cap, *a*. The projection *c*, beneath the shoulder of the screw-cap, is ground to fit tightly the top of syringe barrel when the piston is down. This, with the additional screw-cap *d* at the bottom, hermetically seals the barrel, thereby keeping the piston moist and in good working order for a long time, which is more than can be said of the majority of syringes, whose pistons easily become dry and utterly useless if not frequently used. In case of necessity the syringe may be used as an aspirator, but great care must be exercised to thoroughly cleanse it before again using it for hypodermic injection.

A small loop is left in the pocket-case for hypodermic tablets in the original bottle to take the place of the bottle of morphia solution or powders, which are usually carried.

A Tiemann & Co.'s new sterling-silver male and female *Catheter*, with a flexible jointed end, made in two sections, one nesting within the other, thus economizing space and saving the catheter from damage by pressure of other instruments.

A Weir's *Vaccinating Luncet and Comb*.

An aluminum *Caustic Holder*, which is non-corrodible by nitrate of silver, and which is fitted with an extra male thread to screw into the end of the catheter, if a longer caustic holder is desired. Within the extra male thread is

a female thread into which the probes, tenaculum, aneurysm needle, and double hook in the case can be screwed if a firm handle to either is needed.

On turning over the left-hand flap, *b*, of pocket-case, it discloses loops for the thinner instruments:

1. *Probes*, of which there are six varieties, each five inches in length and fitting a middle joint, with a female screw at each end, to make the probes fifteen inches long when it is desired to explore long sinuses, viz.:

Two sterling-silver probes, one with a large, the other with a small point. The large point, suitably bent and lengthened by other pieces, makes an excellent searcher for exploring the bladder in children.

One very flexible whalebone probe for tortuous sinuses.

One Arnott's grooved probe to act as a fine director in narrow sinuses, and, in case of necessity, for external perineal urethrotomy.

TIEMANN & CO

One combined *porte-mèche*, *c*, and seton-carrier, *b*.

One flexible steel, extra-small Nélaton's porcelain-point (one sixteenth of an inch in diameter) bullet probe, especially useful in locating leaden fragments.

2. An *Aneurysm Needle* with a large eye.

3. A *Tenaculum*.

4. A *Volsella*, or double hook, each fitting into the caustic holder for a firm handle.

5. A combined *Tongue-tie* instrument and strong *Spatula*, which will act as a large blunt dissector or tongue depressor.

6. A combined, strong, spade-shaped *Dissector*, *b*, and sharp medium *Scoop*, *a*.

7. A combined, strong, square, blunt *Dissector*, *b* (useful in raising periosteum), and sharp, fenestrated *Bone Scoop*, *a*.

8. A Gross's *Ear Spoon and Hook*.

9. A combined, large, grooved *Director* and large, dull *Scoop*.

10. A large *Aspirating Needle*, five inches long, for exploring deep tumors, tapping hydrocele, etc. It has a

female thread inside the shoulder, *b*, for screwing on to the hypodermic syringe if suction is required. The shoulder at *b* is for attaching rubber tubing if desired.

11. A combined Post's and Buck's *Pin Conductor* for readily introducing pins in hare-lip suture. The groove of

the needle at *a b* is bridged over, forming a canal, which is closed at *a*.

12. A fenestrated *Punch* fitting into the needle holder for a firm handle for carrying out Neuber's wound draining

without drainage-tube (see article by Dr. A. G. Gerster, "N. Y. Medical Journal," vol. xxxix, No. 10).

Clinical Reports.

ROOSEVELT HOSPITAL.

CLINICAL REMARKS BY HENRY B. SANDS, M. D.

Strangulated Inguinal Hernia.

GENTLEMEN: An interesting case of strangulated hernia was admitted into the hospital last Friday afternoon. The patient was a driver of a beer wagon, who had had a hernia for several years. He had worn a truss, which, he said, broke on the morning of the day of his admission; and, while he was engaged in doing some heavy work, the hernia came down and could not be replaced. When he was brought here in the evening we found upon the right side an oblique inguinal hernia, tense and painful, and reaching down to the scrotum. The usual symptoms of strangulation were present, vomiting being persistent. Ether was administered at nine o'clock in the evening, and taxis, which had already been tried before admission, was repeated without success. Percussion over the tumor gave very little resonance, yet the symptoms were so acute that I thought there must be intestine in the hernial sac. I made an incision over the latter in the usual way, and, on reaching the deeper structures, found that no operation short of opening the sac would avail. The interest of the case turns upon a false inference which I made concerning the nature of the contents of the sac, which, as you are aware, usually contains more or less bloody serum in case the hernia is strangulated. This, in the present instance, seemed to be absent, as no fluctuation could be detected when the sac was exposed. Moreover, the sac was slightly resonant on percussion, indicating the proximity of intestine, while its tension was so great that I was unable to pinch it between my thumb and finger and separate it from its contents. Lest I might wound a possibly adherent coil of intestine, I determined to use a hypodermic syringe and ascertain whether there was fluid in the sac. The result of the procedure was what deceived me. I passed the needle to a depth of half an inch, and, on drawing back the piston, the syringe filled with a fluid which proved to be almost pure blood, having no fecal odor. Now, we frequently notice, in cases of strangulated hernia, that, after the taxis has been employed, the hernial sac contains blood and, inferring that such was the case here, and that the blood withdrawn by the syringe came from the hernial sac, I failed to observe due caution in performing the next step of the operation—namely, that of opening the sac—and accidentally wounded a piece of the small intestine which lay in contact with it. Fortunately, the incision was not extensive; it simply involved the peritoneum, and did not exceed a third of an inch in length. When the sac was laid open, it was found to contain no fluid, being completely filled by a loop of small intestine, which was intensely congested, and in some places ecchymotic. There can be no doubt that the bloody fluid which was withdrawn by the hypodermic syringe came from the in-

terior of the intestine, into which it had been effused in consequence of the strangulation and of the force which had been used in endeavoring to effect reduction. As I have remarked, the wound of the intestine made by the knife was very slight and superficial; but it might well have been serious; and we may learn from the occurrence how careful we always ought to be in opening a hernial sac. The operation presented no other feature of special interest. After the stricture, which was situated in the neck of the sac, had been divided by a hernia-knife, the protruded intestine became less livid, and, a few minutes later, the oozing from the injured part, which had been quite free, ceased spontaneously. Reduction was then effected, and the external wound closed with a continuous suture of catgut. The operation was followed by immediate relief, no unpleasant symptoms occurred, the wound healed by the first intention, and the patient is already convalescent.

Correspondence.

LETTER FROM PARIS.

The Cholera in France; its Comparative Mildness and Tractability.—The Question of its reaching Paris.—Dr. Koch and his Decoration.

PARIS, July 23, 1884.

THE leading medical topic at the present time is the existence of Asiatic cholera in some of the cities in the southern part of France. In view of the advanced state of our knowledge concerning the real nature of infectious diseases, the outcome of investigations made during this epidemic will be looked for with more than usual interest. The epidemic, thus far, has not been a severe one, the total number of deaths not equaling the daily emigration from Marseilles. During the week now ended the average daily mortality has not changed materially, except on one day, when it was so low that the dispatches announced "marked decrease." This morning the Parisian dailies exhibit the heading, "The Slow Epidemic."

The comparatively low rate of mortality can be explained in different ways. In the first place, epidemics, of either the same or different diseases, manifest varying degrees of violence. Again, prompt resort to decided measures for the arrest of an epidemic may exert a powerful influence. In the present instance it is altogether probable that both of these factors can be included in the explanation of the comparatively low rate of mortality. Moreover, the medical management of the patients after they have been attacked may reasonably be expected to do much toward lessening the rate of mortality. During the present outbreak a large percentage of the patients have recovered. Heretofore medicine has been comparatively powerless for affording relief to those who have been stricken with the genuine disease. But here, also, the fact must not be overlooked that success follows the administration of medicine in a far greater proportion of cases when the epidemic is mild, and conditions favoring its continuance and spread are carefully corrected.

The ubiquitous newspaper reporter is here, of course. But exactly where so many sensational reports come from is one of the mysteries of the calling which have not yet been solved, and probably will not be even by bacillus culture and microscopic examination.

It is rather remarkable that so large a proportion of the reports which, up to this date, have appeared in the New York dailies concerning the widespread terror in consequence of the epidemic, more especially in Paris, have been so extremely sensational. This is true, or else the promulgators have been more fortunate in acquiring news than the daily papers published in the capital of France. One might easily infer from some of the dispatches that Paris was fast becoming depopulated. There is nothing apparent here, however, to sustain the inference. To be sure, some have left; others have come; still others have refrained from coming; but Paris to-day presents

an appearance essentially the same as that exhibited in 1883 or 1882, except that its streets are cleaner, because extraordinary precautions are being taken concerning cleanliness.

Is the disease now prevailing in southern France true Asiatic cholera? Fovel said it was not. Koch says it is, and there seems to be no question now that his diagnosis is correct. Fovel, however, saw the *earlier* cases, and committed himself to an opinion. Koch saw cases *later* in the epidemic, when the diagnosis was not difficult. In the minds of reasonable medical men, the result does not argue either in favor of one or against the other investigator.

Has cholera spread from Marseilles and Toulon? It has, but not very far, and only to the smaller towns within a radius of a few miles. In each instance the number of cases has been small, and the authorities have at once had them in charge.

Has cholera reached Paris? No. It can be said, on the best authority, medical and governmental, that, up to the present date, not a single case of Asiatic cholera has occurred in this city. Will it reach Paris? The chances seem to favor the opinion that it will. Marseilles is depopulating itself at the rate of twelve hundred daily, and, of these, seventy come to Paris. It is a reasonable supposition that these seventy belong to the better classes, and that favors the idea that they will not become carriers of the disease. Exactly what may occur it is impossible to predict.

Koch came, and went, and has been decorated. It is a question whether the cross of the Legion of Honor was conferred so much for what Koch had done as to smooth over what the German Chancellor was about to regard as an awful insult given to the flag on the 14th of July. The old man with the gout has terrible twinges occasionally, and, if a piece of red ribbon in the lapel will serve the purpose of killing two birds with one stone, who can blame the foxy French for honoring the equally shy, scientific Koch?

However, Koch submitted to fumigation like a man, when he returned, said that if there was any cholera about him it was in his intestines, and went his way like a "plumed knight," wrapped up in the mysteries of bug-hunting.

Has he found the specific *microbe*? It is safe to say that no one knows—not even Koch. Micro-organisms elude proof positive with as great facility as the mosquito escaped the thump of the towel of Artemus Ward, who "hit the identical spot where the little gray cuss sot."

Besides, Koch will not bring his little gray cuss out, if he has got him, until the Frenchman has writhed long under the agony of an error in diagnosis.

Note on Dr. Van de Warker's Case of Laparo-hysterectomy.—Since our last issue went to press, containing an account of "A Successful Case of Laparo-hysterectomy for Uterine Fibroids," by Dr. Ely Van de Warker, of Syracuse, N. Y., we have received the following from the author:

Note, July 29th.—The ligature upon the uterine stump came away early in April. The lower extremity of the abdominal wound is now defined by a central depression 1 cm. in depth, at the bottom of which the uterine stump appears, slightly elevated, conical, smooth, and red, with a central opening that will receive a small probe, which corresponds to the canal of the cervix. The stump is firmly adherent to the abdominal wall, and will evidently never recede into the abdominal cavity. A light dressing of absorbent cotton, renewed twice a day, is required to keep the cavity dry. Mrs. B. has consented to have the uterine stump covered when the weather becomes cooler. The operation will consist in raising a flap of the integument upon each side of the abdominal depression and bringing them together over the stump. In this manner a condition that annoys the patient very much may, it is hoped, be removed.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & CO.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, AUGUST 9, 1884.

A MULTITUDE OF COUNSELORS ARRAYED AGAINST THE
CHOLERA.

WE have always given the gentleman whose letter from Paris appears in this issue of the journal credit for an exceptional amount of steadiness, and we have seen him show it under somewhat trying circumstances; but we now perceive that we have heretofore failed to do him full justice in that regard, for we have not had the slightest idea that he was the sort of man who could play the optimist amid such goings on as our French contemporaries tell us are now the order of the day in Paris in so far as the cholera is concerned. We are glad to see testimony to the effect that the gravity of the situation in France has been in some respects overdrawn, but, while the present decline in the virulence of the epidemic in Toulon and Marseilles must be said to be of cheering import, we do not see how the conclusion is to be escaped that at least there is enough of danger to the capital to have created a decided stir, not only with the general public, but also in the ranks of the medical profession, as exemplified by the avalanche of infallible preventives and cures that have met with more or less attention. Thus far in the ordeal, the medical profession in France, as represented in the leading societies, has borne itself with most admirable discretion. The problems presented by the outbreak in Toulon and Marseilles have been dealt with in a way that must be called exceedingly creditable. We have met with no indications of any such wrangling as took place last summer when the Egyptian outbreak was under consideration, nor has there seemed to be any disposition to conceal or pervert the facts as to the prevalence of the disease. The physicians and the sanitarians of France have set to work to renew their study of cholera in a matter-of-fact and business-like way, without posing either as skeptics or as alarmists, and, whenever local zeal has outrun discretion, the voice of the *Académie de Médecine* has been raised promptly in furtherance of the most reasonable and practicable course.

The course pursued by the French medical journals is to be spoken of in like terms. They have given very satisfactory accounts of the progress of the epidemic throughout, and they have not gone out of their way to advocate crotchets. Not the least commendable of the features that have marked the policy of the journals in question, it seems to us, is the disposition lately shown to make merry over the wild and chimerical suggestions with which the *Académie* has found itself afflicted. The moral effect of this way of treating the matter can not fail to be good. Apart from any such motive as this, however, there is indeed enough in the proposals made public to provoke mirth, if we may judge from an amusing account given by the "Union

médicale" of a recent meeting of the *Académie de Médecine*. The number of communications received by the secretary, all of which embodied wonderful propositions for the prevention or cure of cholera, was so great that that officer, after having read a few of them, felt compelled to desist, remarking that to read them all would take up the entire time of several meetings. These communications came from physicians and from men in other callings, from men and from women, each of whom was hot-headed in advocating his or her particular sovereign remedy. One of the correspondents urged "dry cleanliness" as the solution of the problem, meaning the omission of water and every other liquid in the toilet. Another proposed washing out the digestive tract with iodized water. A third recommended the internal and external use of oil of turpentine. A fourth thought it necessary to go deeper, and pursue the *microbe* in the blood itself, by means of intravenous injections of oxygenated water. A fifth upheld the policy of expelling the germ by a sweating-out process induced with pilocarpine. One ardent soul, more radical than the others, put his trust in the action of cold, and proposed to get the better of the cholera by creating an artificial winter—a feat easily enough accomplished, he said, as it was only necessary to "suppress the sun," which could be done by sending a part of his rays back into space with the aid of a combination of mirrors, and by absorbing the rest! Another correspondent, perhaps, as the "Union" suggests, a trifle malicious, called for a convention, to be made up of all physicians who professed to have a sovereign remedy against the disease.

But the crisis was reached when the secretary brought forward a sealed box said by the person who had sent it to contain the true germ of the cholera, which he termed the "choliferous mucus." Whether impelled by his own curiosity, or inspired with an admirable piece of tactics to secure his release from the irksome position in which he must have felt himself, the secretary was gravely proceeding to open the box when from all quarters of the house he was greeted with the cry, "Don't open it!" His hand was stayed, his scheme was thwarted, and this particular Pandora's box remained unopened. It remained an open question with the Academy what should be done with so dangerous a present.

A DANGEROUS SUCCESS.

In a recent issue of the "Medical Times and Gazette," Mr. Lawson Tait relates the case of a woman, thirty-two years of age, who presented herself at the Birmingham Hospital for Women, complaining of constant pelvic pain since her last confinement, much aggravated by her having "strained herself" six weeks before. The uterus was found somewhat fixed, and there was a cystic mass behind it very tender on pressure. Mr. Tait states that the physical signs were precisely those that would have led him to diagnose a pyosalpinx or hydrosalpinx, only it happened that the patient had not suffered much at menstruation. He therefore made no diagnosis, but advised abdominal section. The patient having consented, he opened the abdomen, and found "a good deal of matter in the pelvis, and

a coil of intestine adherent in the *cul-de-sac*." He "undid the adhesions without much difficulty, and closed the abdomen." On the twentieth day the woman left the hospital, and has had no trouble since.

Mr. Tait briefly reviews the points in the case, and speaks of the error into which he would have fallen if he had taken it for granted that the case was one of pyosalpinx or of hydro-salpinx, and acted as some advise—i. e., tapped from below. "I should have done no good," he says; "I should probably have made my patient worse; I might even have killed her. On the other hand, following my rule of opening the abdomen I was able, with very little difficulty, to cure completely a condition which distressed the patient, which put her in constant risk of her life, and for which no other remedy was possible."

Much as we admire Mr. Tait's achievements with laparotomy, it is difficult to avoid the feeling that the tendency of such statements and comments as we have quoted is to foster the view that the operation is indicated in the general run of cases of pelvic exudate with encysted fluid, provided it distresses the patient. Abdominal section, shorn though it has been of the greater part of its peril, and in great measure by the admirable work of Mr. Tait, does not seem to us to have yet become so innocent a procedure as to justify the inference which some will be apt to draw from the case in question. Looking at the matter from that point of view, it may well be questioned if the successful issue of the case is not fraught with danger.

MINOR PARAGRAPHS.

HYDROTHERAPEUTICS AT SARATOGA.

IN spite of the popularity of some of our American watering places, and the vague trustfulness with which patients with chronic ailments resort to them, it must be said that, in comparison with those of other countries, our resources in the shape of mineral springs have not hitherto been turned to account therapeutically in any way deserving to be called systematic or intelligent. It is undoubtedly true that in certain parts of Europe the powers of the mineral waters are magnified far beyond their real worth, and the indications for their therapeutical employment over-refined, but it is very certain that we have erred in the opposite direction. It is on all accounts to be desired that a systematic study should be made of those of our waters that have been conceded to have any just pretension to definite medicinal properties, and we are glad to learn, therefore, that one of the resident physicians of Saratoga, Dr. R. C. McEwen, is about to enter upon the study of the Hathorn spring somewhat after the manner of the bath physicians of Europe.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending August 5, 1884:

DISEASES.	Week ending July 29.		Week ending Aug. 5.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	0	0	1	1
Typhoid Fever.....	21	9	22	6
Scarlet Fever.....	50	9	37	5
Cerebro-spinal meningitis.....	5	5	3	3
Measles.....	129	27	84	20
Diphtheria.....	31	19	26	9

The Cholera has continued to abate in France during the week, and the prospect now seems to be fair that the decline will prove definitive. On the other hand, the disease has broken out, although in a very small way, in a number of Italian towns. The French Government, it is said, has demanded the discontinuance of the quarantine along the frontier, and threatens "reprisals" in case of a refusal.

Yellow Fever.—In consequence of the prevalence of this disease in the northern part of Mexico, it is stated, railway trains arriving at the frontier are to be inspected under the direction of the collector of customs at El Paso. Information received by the Surgeon-General of the Marine-Hospital Service from the State Board of Health of California, to the effect that a Spanish opera troupe had been allowed to pass Nogales, although there had been several deaths from yellow fever among the members of the troupe, led the Surgeon-General to direct a prompt investigation of the matter, and the dismissal of the inspector at Nogales in case it should appear that he had been negligent; but subsequent advices are to the purport that the troupe was detained, and that there was no occasion for the fear of the members spreading the disease.

The Lehigh Valley Medical Association will hold its fourth annual meeting at Mauch Chunk, Pa., on Tuesday, the 19th inst., instead of on Wednesday, the 20th, as had been announced. The annual address will be given by Dr. Theophilus Parvin, of Philadelphia.

The State Board of Health of Kentucky has issued a circular, signed by its president, Dr. Pinckney Thompson, and its secretary, Dr. J. N. McCormack, giving very sensible directions for the guidance of the people of the State in the matter of preventing the cholera.

The Connecticut State Board of Health reports, through its secretary, Dr. C. W. Chamberlain, of Hartford, a favorable condition of the public health for the month of June, although diphtheria still lingered in Hartford. The summer diarrheal diseases appeared early, but have not been very prevalent. We are indebted to the secretary for the copies of the board's "Instructions for Disinfection" and its "Suggestions concerning Cholera." Both these pamphlets contain advice and information which can not be laid before the community too often.

The "Canadian Practitioner" announces material changes in its editorial staff. Dr. Cameron and Dr. Nevitt retire, and their places are taken by Dr. J. E. Graham and Dr. W. H. B. Aikins, who, together with Dr. A. H. Wright, are to be the editors and proprietors.

A Novelty in Medical Journalism.—In its issue for July 26th the "Lancet" publishes an "annotation," entitled "Oleo-margarine," and credits it to itself.

M. Pasteur's Experiments on Hydrophobia, we learn from the "Union médicale," are to be continued on a portion of an estate set apart for the purpose by the French Government.

An Extraordinary Advertisement appears in one of the Fort Wayne, Ind., newspapers, setting forth the advantages of a certain "private sanitarium and lying-in institute." The proprietor's modesty and his elegance of diction are both conspicuous in the following passage: "My success in cases of confinement is unprecedented, and will attend to cases when called." The last item in the advertisement reads: "Money to loan."

The State Lunatic Asylum at Utica having been made the subject of a number of injurious allegations by one Louis A. Tourtellot, who failed to appear before the Board of Managers after having been served with a subpoena, the board has resolved

to apply to a judge of a court of record for a warrant directing the sheriff to compel him to attend. It looks, therefore, as if the charges made by Tourtellot were fanciful if not malicious.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 27, 1884, to August 2, 1884:*

HEAD, JOHN F., Colonel and Surgeon. Ordered to Portsmouth, N. H., to meet the Greely party, and consult upon the proper course of treatment, with a view to the entire restoration to health of Lieutenant Greely and the men of his command. Par. 14, S. O. 177, A. G. O., July 30, 1884.

WRIGHT, JOSEPH P., Major and Surgeon. Sick leave of absence extended three months on surgeon's certificate of disability. Par. 12, S. O. 176, A. G. O., July 29, 1884.

WOODWARD, JOSEPH J., Major and Surgeon. Sick leave of absence extended six months. Par. 9, S. O. 178, A. G. O., July 31, 1884.

McELDERY, HENRY, Captain and Assistant Surgeon. So much of Par. 12, S. O. 165, A. G. O., July 16, 1884, as assigned him to duty in Department of the East, is revoked, and he is ordered to report in person to the Surgeon-General of the Army for duty in connection with World's Industrial and Cotton Centennial Exposition at New Orleans, La. Par. 12, S. O. 178, A. G. O., July 25, 1884.

FINLEY, J. A., Captain and Assistant Surgeon. Granted leave of absence for one month, with permission to apply for one month's extension, to take effect about Sept. 1, 1884. Par. 2, S. O. 91, Headquarters Department of Texas, July 22, 1884.

TAYLOR, A. W., First Lieutenant and Assistant Surgeon. Ordered for temporary duty at Fort Riley, Kansas. Par. 1, S. O. 153, Headquarters Department of the Missouri, July 29, 1884.

GANDY, C. M., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month, to commence between August 15th and 30th, provided he furnish medical attendance at Fort Brady, Michigan, during his absence. Par. 5, S. O. 154, Headquarters Department of the East, July 30, 1884.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the Navy during the week ending July 26, 1884:*

HARMON, G. E. H., Passed Assistant Surgeon. Ordered to temporary duty at Norfolk Navy Yard.

Society Meetings for the Coming Week:

TUESDAY, August 12th: Medical Societies of the Counties of Rensselaer and Ulster, N. Y.; Newark, N. J., Medical Association (private); Trenton, N. J., Medical Association (private).

WEDNESDAY, August 13th: Medical Society of the County of Cayuga, N. Y.

Proceedings of Societies.

NEW YORK OBSTETRICAL SOCIETY.

A STATED meeting was held March 18, 1884, W. M. POLK, M. D., President, in the chair.

Ovariectomy.—Dr. J. B. HUNTER narrated two cases of ovariectomy, in both of which the patients died. The first case was that of an unmarried woman, thirty-five years of age, who for nine months (and, she was certain, for not more than nine months) had suffered from pain in the pelvic region. A tumor was noticed in the right side for the first time last December. She came under Dr. Hunter's care March 1st. After a careful

examination he made a diagnosis of ovarian tumor, probably malignant. The patient was very much emaciated, and had the appearance of a woman suffering from a malignant disease. The tumor filled the whole abdominal cavity, and caused much pain by pressure. The patient's appearance was that of a woman of sixty-five. A consultation was held with two of his colleagues at the hospital, and they agreed that an operation was demanded, although the prognosis was unfavorable. There was some albumin in the urine. The operation was performed on the 10th of March. The usual abdominal incision was made. Some ascetic fluid was found, and a tumor of large size on the right side, extending up to the diaphragm and attached to the abdominal walls and the intestines. The contents were evacuated, and the adhesions separated without much difficulty or hemorrhage. The pedicle, which was short, was transfixed and tied. Another tumor, of about half the size of the first, was then found upon the left side, including the left ovary. Both tumors were multilocular. Within the left tumor were several papillomatous, cauliflower-like growths, projecting from the walls. A small portion of the left tumor could not be removed, as it was very firmly adherent to the pelvic fascia. The operation was not of long duration, but the patient's condition was very low; she had had a high temperature for some time before, and death took place ten hours after the operation. There had been but little hemorrhage. The specimens had been examined by Dr. Welch, who pronounced the growth malignant.

The other case was that of an unmarried woman, eighteen years of age, who for four years had noticed some abdominal enlargement, which had increased decidedly during the last year. She had been a patient of Dr. A. N. Brockway. For the last year there had been a constant dull pain in the pelvic region, and for six weeks past a severe pain, requiring morphine for its relief. The tumor was so tense as to be readily mistaken for a fibroid. The patient had menstruated regularly, but had a metrorrhagia, lasting a month, one year ago. Ether was given February 28th, as a satisfactory examination could not be made without it, in consequence of the pain it caused. The mass was central, and so hard that it was still considered doubtful whether it was uterine or ovarian. The depth of the uterus was two inches and a half. From that time until the date of operation, March 12th, the temperature varied from 100° to 104°, with nausea and vomiting, notwithstanding the use of the cold coil and quinine, and constant severe pain. The tumor increased in size, and the diagnosis of a suppurating ovarian cyst was then made. Dr. Thomas and Dr. Emmet agreed in the diagnosis and advised immediate operation. On making the usual abdominal incision a tense cyst was reached, which was so vascular and hard that it had the appearance of the uterus. A small puncture with Peaslee's needle was made, and a jet of extremely fetid pus escaped. None of the fluid was allowed to enter the abdominal cavity. The patient was turned on the side, and the cyst washed out thoroughly with carbolyzed water until the fluid returned clear. Then, on making an exploration, the cyst was found firmly adherent to the intestines, to the abdominal walls, and apparently to the uterus and other pelvic viscera. Very little investigation showed that it was impracticable to remove it. The abdominal wound was sewed up in the usual way, and the edges of the sac were stitched to the lower portion of the wound, so as to separate the cavity of the cyst entirely from the abdominal cavity. The operation lasted about an hour. There was but little hemorrhage. The patient rallied, but died early the following morning. The pulse before death was strong and rapid, and the temperature in the vagina rose to 107°.

The following report of the post-mortem examination had been furnished by Dr. W. H. Welch:

"Upon careful examination, it appears that the tumor is formed partly by a suppurating intra-ligamentous ovarian cystoma and partly by an intra-peritoneal abscess. The cystoma originates from the right ovary, which is therefore not to be discovered in the specimen. The left ovary is present, buried in adhesions. The inner surface of the posterior wall of the cyst is lined by cylindrical epithelium. In front, where the posterior surface of the uterus forms a part of the cyst-wall, there is no epithelial lining. The formation of the tumor may be explained as follows: There grew primarily a cystoma from the right ovary, between the layers of the right broad ligament. This cystoma consists of one large main cyst and several secondary cysts, which can still be made out, partly with purulent contents. Suppuration occurred in the main cyst, which resulted in a partial destruction of its walls, and the formation of an intra-peritoneal abscess, shut in by adhesions, but communicating with the main cyst. The adhesions encapsulating the intra-peritoneal abscess were so formed as to include the abdominal extremities of both Fallopian tubes, the mouths of which opened into the abscess cavity, and hence indirectly into the cystoma. The wall of the cystoma corresponding in its relations to the posterior wall of the uterus was entirely destroyed, so that here the uterine wall is also a part of the cyst-wall. The inner wall of the cystic tumor is therefore partly peritoneum and partly the mucous layer of a cystoma, but, except by microscopical examination, it is not easy to tell how much of the common cyst belongs to the cystoma and how much to the intra-peritoneal abscess. The ovarian origin of the tumor is proved by its multilocular character, by the lining with cylindrical epithelium, and by the absence of the right ovary. The intra-ligamentous mode of growth is proved by the peritoneal covering of the surface, and by the incorporation of the Fallopian tube and the round ligament in the cyst-wall. The partial formation of the cyst out of an intra-peritoneal encapsulated abscess is proved by the defect of the cystoma-wall in places and its replacement by peritoneum (posterior wall of uterus), and by the communication of both Fallopian tubes with the interior of the cyst, a communication difficult to explain upon any other supposition. Around the margins of the openings of the tubes into the cyst the fimbriae can still be made out, so that dilated tubes form no part of the cyst."

Had it been possible to make an examination two or three weeks earlier, the patient's life might probably have been prolonged by an operation. If, however, tapping had been resorted to as a means of diagnosis, the cyst being so tense, some of its putrid contents would doubtless have escaped into the abdominal cavity and caused fatal peritonitis.

Dr. J. E. JANVRIN asked of what the second patient really died; whether of shock, or of septicæmia which had existed for some time previous to the operation, as indicated by the persistent high temperature. He was rather of opinion that death took place from septicæmia, perhaps aided somewhat by the shock of the operation.

Dr. HUNTER agreed in this opinion, and said he thought that if the patient had been let alone she would certainly have died, within two or three days, of septicæmia.

The PRESIDENT asked Dr. Hunter, with regard to his first case, what he thought would have been the effect upon the ultimate result of the case of leaving the small, most firmly adherent portion of the cyst alluded to in the pelvic cavity.

Dr. HUNTER replied that it would in all probability simply have remained adherent without undergoing decomposition. He did not think it called for drainage.

The PRESIDENT said he had had a case which in many respects presented almost the identical features observed in Dr. Hunter's first case. A small portion of the sac had to be left.

The patient died on the sixth day after the operation, of shock, and the condition found at the post-mortem showed that the result would not have been changed if a drainage-tube had been introduced. The patient was older than Dr. Hunter's, being sixty-seven. This fact would probably render adhesive inflammation less likely to take place.

Dr. JANVRIN had assisted at an ovariectomy about a month ago which terminated fatally. The patient was unmarried, forty-five years of age. He saw her only the day before the operation. The physician and patient stated that the abdominal tumor had been present only six months. The tumor, however, was of immense proportions, and the patient was extremely emaciated and weak. Dr. Janvrin found evidence of more or less adhesions and a large firm mass in the right *cul-de-sac* which was thought to be a portion of the ovarian tumor above. It was firmly impacted, it being impossible to dislodge or move it. The uterus was normal, and lay a little to the left and anteriorly. The operation was done at St. Elizabeth's Hospital. At first an incision about two inches and a half in length was made, and the tumor found apparently to be uniformly adherent. In trying to separate the adhesions of the sac from the abdominal parietes the cyst was very slightly torn and a hole made of the size of a pin's head into its cavity. Dr. Janvrin then advised immediate tapping, which was done with a large trocar and cannula. The contents were found to be colloid in character. The adhesions were so extensive that the incision was necessarily extended nearly up to the umbilicus. A great deal of difficulty was experienced in fully detaching the cyst from the parietes, principally on account of its soft and friable state. Finally it was thoroughly removed. Unavoidably some of the colloid material entered the peritoneal cavity. The entire cavity was thoroughly washed out with hot water slightly carbolicized. The tumor grew from the right ovary, and, in extracting it, a small rent was made in the broad ligament from which a little hæmorrhage took place. It was controlled by two ligatures. The cavity having been washed out, as before stated, and being perfectly clean, the incision was closed. The operation consumed forty-five minutes. During the operation the pulse disappeared and the patient seemed to be dying. Ten or twelve hypodermic injections of brandy were given, the feet were elevated, and, as the legs were extremely œdematous, rubber bandages were sent for, with which they were wrapped, forcing the blood and serum into the body. The pulse almost immediately became perceptible, and the patient was put to bed. Reaction took place in about three hours. The drainage-tube was left in. At the end of forty-eight hours it became evident that there was more or less serum in the abdominal cavity, as indicated by septic symptoms. The dressings were raised and a pint of serum was withdrawn. The patient lived nine days, and finally died, apparently of exhaustion, all symptoms of septic poisoning having disappeared about the fourth day. There was no further accumulation of serum. The points of interest in the case were, the immense size of the tumor, its colloid character, the extreme feebleness and almost moribund condition of the patient during the operation, and the very favorable effect which applying elastic bandages to the extremities had by forcing the serum back into the general circulation, answering almost the same purpose as transfusion, which had been suggested during the operation.

The PRESIDENT asked Dr. Janvrin whether he thought, in view of the extensive adhesions, the operation should have been done. He made the inquiry because he himself had been placed in a similar position, and he would like to know the opinion of others.

Dr. JANVRIN replied that he had seen many cases in which the adhesions were as extensive, and yet the operation proved

successful. In this case the patient was sinking very rapidly, and an operation offered the only chance of recovery; it was for that reason that he advised the doctor to remove the tumor as soon as possible.

The PRESIDENT remarked that, where the adhesions were extensive and firm, one could not tell beforehand how long a time the operation would require, how much handling would be necessary, nor the possible amount of the hemorrhage, and the patient's chances were consequently likely to be greatly diminished.

Dr. HUNTER mentioned a case in which the adhesions were very extensive in every direction, and the patient recovered; and another of a similar nature, operated upon by Dr. Thomas, in which the adhesions extended to the diaphragm. The patient surprised everybody by making a good recovery.

The PRESIDENT remarked that in his experience with such cases the adhesions had been principally in the pelvic cavity, but, if they occurred higher up, and even on the diaphragm, they were less vascular, the operation was not so bloody, and occasioned less shock. Their extent, their vascularity, and the great length of time required for their separation within the pelvic cavity, and the attendant shock, made it questionable whether firm adhesions should be interfered with in this locality, especially if they were extensive.

Dr. JANVRIN thought that in such a case the upper portion of the sac might be removed and the lower part, where it was most firmly adherent, be allowed to remain and drainage be established. He had done this in several cases.

Dr. P. F. MUNDÉ had operated upon a patient a little more than a year ago in whom two tumors were present—one high in the abdominal cavity and the other firmly adherent to the entire pelvic cavity. No particular difficulty was experienced in removing the first tumor, except that the care with which it had to be stripped from its extensive attachments required considerable time. The second tumor was of about the size of a large cocoa-nut, had apparently developed within the broad ligament, and had to be seared off with Paquelin's cautery from the posterior surface of the uterus down to the *cul-de-sac*. No pedicle was left. Some large arterial twigs in the seared surface were tied by deep sutures. The abdominal wound was closed and a drainage-tube inserted. Dr. Mundé had since concluded that he had closed the wound too soon; he should have waited until it was certain that every bleeding point was permanently secured, for the patient was in good condition, although the operation had lasted an hour and a half. She rallied well, with scarcely any shock. But a good deal of bloody serum escaped through the drainage-tube, and, after twenty-four hours, her condition suddenly changed, the pulse went up to 150, and symptoms of collapse appeared. In spite of all efforts at restoration, she died the next morning. A post-mortem was not allowed, but Dr. Mundé was of the impression that secondary hemorrhage had taken place, and that in similar cases it was better to prolong the operation and take the chances of shock, in order to make sure that all bleeding was permanently arrested.

The PRESIDENT said the question which had been in his mind was whether it was good practice to persist and break up all the adhesions where they were very extensive. It seemed to him, from the discussion which had taken place, that the method suggested by Dr. Janvrin was the proper one to pursue—namely, to remove the upper portion of the sac, if possible, and leave the portion firmly adherent within the pelvis and wash it out. He had observed the plan suggested by Dr. Mundé of persisting in removing all the sac down in the pelvis and waiting until all oozing had ceased in two cases, and he lost both of the patients from secondary shock. Not a teaspoonful of serum had exuded

in either case. He believed that both patients would have been saved had he been less anxious to get away all the stump.

Dr. MUNDÉ had operated upon a patient a year and a half ago, in which case the sac was so broken down that it had to be removed piecemeal. The patient died of shock. He therefore thought the suggestion which had been made, to leave a portion of the firmly adherent sac and establish drainage, a good one, as subjecting the patient to a less degree of shock. He had observed this plan in one case, and the patient recovered.

With regard to Dr. Janvrin's second case, Dr. F. P. FOSTER asked whether the immediate beneficial effect of the application of the rubber bandage was not due rather to forcing the blood than the serum from the extremities directly into the general circulation.

Dr. A. JACOBI said that, while the serum could not be forced directly from the tissues in which it was found into the general circulation, it required but a short time for it to reach it indirectly, under pressure, for the lymph-ducts terminated in the subcutaneous tissue with open orifices; and, although it might have swelled the volume but slightly, it was known, from the results of transfusion of salt water, that a few ounces would have the effect of restoring the patient. The fact that the oedematous limbs were found to be reduced to their normal size after removal of the bandages showed that the serum must have gone to the circulation within the body. He thought, therefore, that some of the effects were due to the return of the serum as well as of the blood to the general circulation.

The Relation of Over-nutrition after the Acute Fevers of Childhood to Bone Disease.—Dr. JACOBI said he would refer to a class of cases which were not very uncommon, and which were interesting because of their connection with a number of physiological and pathological questions. A very simple and illustrative case was the following:

Some time ago a girl, eleven or twelve years of age, was present at his clinic for a swollen right humerus at its lower portion. The swelling was very slightly painful. There was a cicatrix about the middle of the arm, which had formed about six months before, after a sinus had lasted six years. A fistula opened an inch and a half above the elbow, on the anterior aspect, which led down to about the middle portion of the epiphysis, apparently extending to the periosteum only. It was stated that the humerus began to swell when the child was four years old, and very soon after she had gone through a severe attack of typhoid fever. The question arose, Had this swelling of the bone and periosteum anything to do with the typhoid fever? Dr. Jacobi thought it had, for reasons which he would state. While he might not be able to say anything that was not known to every person present, still the case was of interest in connection with a number of others which he had seen, and which were very interesting to him, particularly so because they opened up the question of the cause of quite a large number of cases of a similar description. There was one peculiar fact in the development and growth of children, which was known to physicians and also to the laity, that children not only appeared very tall after having gone through a severe illness, and particularly through a severe infectious disease, but they were really taller than before the sickness, and they grew very rapidly for a short time during and after such infectious disease. The growth or tallness was not only apparent, from the patient having become thin, but by measurement it could be shown that they actually were taller. The body became taller by an elongation of the bones; the bones grew by a rapid proliferation about the cartilage which separated the epiphysis from the shaft. If the bone grew, it must be in consequence of a nutritive process, which might become an irritative process, in that neighborhood. And the question arose whether high fevers,

and infectious fevers particularly, had not the effect of producing such irritative disorder as proved under certain circumstances a cause of increased nutrition. Observation showed that after all cases of infectious disease in particular the epiphyses and the adjoining cartilages were very hyperæmic. In such localities, if a post-mortem examination were made, the blood would be found to ooze out, and where there was much blood there was at least an opportunity for over-nutrition. In rachitical bones we knew that the intense growth and thickness were due to such over-nutrition. Thus it was that after most infectious fevers not only the epiphyses were apt to grow thicker, but also the diaphyses to grow longer, in consequence of the nutritive irritation of the cartilage (and periosteum). In cases in which the nutritive disorder, the hyperæmia, was not limited to its physiological condition, where it was a little more than physiological, it became pathological. In most cases the over-nutrition and growth ceased after a while and returned to the normal state, but in others they were carried to such an extent as to become pathological and cause necrosis. Such over-nutrition of the epiphyses was one of the forms of so-called "growing-pain." Growing-pains occurred very frequently after a severe illness, and especially after a severe attack of an infectious fever, and were due to hyperæmia which might amount to inflammation. The other forms of "growing-pain" were either rheumatic or neuralgic in character.

The PRESIDENT understood Dr. Jacobi to mean that the necrosis occurred in these cases merely in consequence of over-nutrition, which became pathological, and in the absence of syphilis or inherited tendency. He would ask how the fact was to be explained that in rachitical children this condition rarely occurred.

Dr. JACOBI replied that the character of the disease changed with the exciting cause. The syphilitic bone, for instance, differed from the scrofulous bone, and again from the rachitical bone. The influence referred to as springing from infectious diseases and the rachitic tendency were rarely combined in producing their effects upon the epiphyseal cartilages, for the infectious diseases usually occurred at an age when the rachitic disease had already healed and the bones had become eburnated, preventing such elongation.

B. F. DAWSON, M.D.,

FRANK P. FOSTER, M.D., *ex officio*,
Committee on Publication.

Reports on the Progress of Medicine.

GYNÆCOLOGY.

By ANDREW F. CURRIER, M.D.

The Mechanical Treatment of Amenorrhœa.—The fact is, as Dr. J. H. Carstens remarks ("Am. Jour. of Obstet.," Nov., 1883), that amenorrhœa is only a symptom, and all scientific treatment of it will have its cause in view. Sometimes this is hard to find, and the experimental use of the various emmenagogues may end in failure. The author is an advocate of rapid dilatation, for the purpose of recalling or of increasing the menstrual flow, and uses for that purpose the two-bladed dilator of Nott. The operation, he says, is harmless, but he admits that it is painful. He has never seen any bad results from its use. [We can not forbear to remark that this procedure is not always quite innocent in hands less experienced than the author's, and too great caution, we believe, can not be exercised in its prac-

tice, not only by the inexperienced and inexpert, but also by those whose experience is mature.]

Non-puerperal Pelvic Lymphadenitis and Lymphangitis.—Dr. Paul F. Mondé (*Ibid.*, Oct., 1883) contributes a very interesting and a very suggestive paper on a subject which has hitherto been overlooked by gynæcologists amid the uncertainty and vexatiousness of the investigations concerning pelvic peritonitis and cellulitis. The author assumes that poisonous or inflammatory influences may be as surely transmitted from the uterus or vagina to the system at large, by way of the lymphatics, in the non-pregnant as well as in the pregnant woman, although the conditions for accomplishing this end are, of course, more favorable in the latter than in the former. Upon this assumption he founds the existence of the diseases in question, one of the prominent phenomena of which is swelling of the uterine lymphatic vessels and glands. Vaginal exploration in conditions like those in question have revealed to the author an exceedingly tender, hot, and puffy parametrium, without any distinct plastic effusion or general elevation of temperature. The uterus is swollen but movable, and motion causes pain. The ovaries are swollen and tender. In some cases, also, there are small indurations on either the anterior or posterior surface of the uterus. Backed by Courty and Carreau, the author feels justified in the conclusion that the condition before mentioned is evidence of the diseases referred to, and he details six cases in which he was positive that his diagnosis was correct. He refers to the anatomical investigations by Championnière and Leopold, who have so brilliantly demonstrated the lymphatic system of the female pelvic organs, and with commendable frankness publishes a personal communication from Leopold, in which that gentleman questions the possibility of feeling non-inflamed, merely distended lymphatic vessels through the vaginal roof. The conclusions of the author are: 1. That an inflammation of the pelvic lymphatic glands and vessels occurs in the non-puerperal state more frequently than is commonly supposed. 2. That this affection stimulates chronic pelvic peritonitis. 3. That these inflamed lymphatics (in spite of what Leopold says) can be felt through the vaginal roof. 4. That the affection may or may not depend upon uterine disease. 5. That its treatment resembles that for chronic pelvic inflammation, the primary focus of irritation being first removed.

The Advantage of Drainage in Suppurative Pelvic Peritonitis and Cellulitis.—Dr. A. Y. P. Garnett (*Ibid.*) agrees with Dr. Emmet as to the supreme importance of these morbid conditions, and gives in detail the history of a case which furnished the phenomena so familiar to every one who has studied these conditions. The case was peculiar in the existence of deep sinuses, which opened externally upon the abdominal surface, one opening being in the linea alba, one inch below the umbilicus, and the other four inches to the right and below the first, in the right iliac region. Drainage was effected by making a counter-opening in the vagina, a blunt-pointed probe being carried from the abdominal opening through the *cul-de-sac* of Douglas, and thence into the posterior fornix vagina. The lower opening was sufficiently enlarged to admit of the passage of a drainage-tube, which protruded from the vulva. Irrigation was practiced from time to time, and after five weeks the drainage-tube was removed. In three weeks more all the sinuses were closed. The patient eventually recovered entirely. The author lays down the broad rule for all cases of suppurative cysts of the broad ligaments, or elsewhere in the pelvic cavity, in case abdominal section is not decided upon, to puncture through the vagina and introduce a drainage-tube.

The Differential Diagnosis of the various Forms of Fibroid Tumors of the Uterus.—Dr. Alfred Meadows, addressing the British Medical Association ("Brit. Med. Jour.," Oct.

13, 1883), observed, as to the progress of knowledge in this direction, that it could now be decided with considerable precision when, and in what cases, interference was justifiable; and whether this interference should consist in extirpation of the tumor, or in what he called physiological starvation—that is, the removal of the ovaries and the stoppage of the blood-supply to the tumor. He objects to the proposition of Lawson Tait, that uterine fibromata should be classified according to their individual character, without reference to their relation to the uterine walls. Clinical experience, he thinks, will sustain the old classification, in preference to the one proposed by Tait, which lacks clinical precision, and is only of post-mortem interest. The rate of growth and the situation of these tumors seem to have a bearing upon their character, those which are interstitial or submucous and of rapid development abounding in cellular elements, while the subperitoneal are more fibrous in character. Of the three groups, under the old and (by the author) approved classification, those of the interstitial variety grow most rapidly, and hence are largely composed of cellular elements. All the varieties are much more commonly developed from the fundus and body of the uterus than from the cervix, and more frequently from the anterior than from the posterior wall. The symptoms are classified under three heads: 1. Disordered menstruation; 2, irregular discharges of mucus or of blood; 3, pain. The difference in degree of these symptoms affords valuable indication as to the site and character of the growth. The two chief symptoms, in the author's experience, bear an inverse ratio to each other—the greater the one, the less the other. He has also observed that, if the tumor gives rise to great pain, it will usually be found to have developed on the peritoneal side of the uterus, while, if the discharge is great, the mucous side is usually concerned. The interstitial growths are akin to the submucous in the matter of discharge, though this is not usually so abundant. When a submucous tumor projects into the vagina, a sloughing process is often instituted, and under such circumstances the condition may be mistaken for cancer, though careful examination will reveal the ring of sound cervical tissue through which the tumor is protruding. If the growth is subperitoneal, the pain from it will be more severe if it is located on the anterior than if on the posterior wall, and the same condition obtains the nearer the growth is to the fundus. The pain is caused by interference with more or fewer of the branches of both the sympathetic and the cerebro-spinal nervous systems, and there is nothing peculiar in its character. When a vaginal examination is made, a hard and insensitive condition of the cervix renders the presence of a subperitoneal fibroid probable. If the condition is simply that of flexion of the uterus, both the body and the cervix will manifest the ordinary softness and tenderness of those parts. By using the sound, a tumor can be accurately differentiated from flexion of the uterus by means of the two factors, viz.: the direction which the sound takes, and its motion or lack of motion as uterus or tumor is touched. In the differential diagnosis between ovarian and fibroid tumors, when both are small, the pain in the former is unilateral, in the latter it is central. The ovarian is also softer and more elastic than the fibroid tumor. If the growth is a large one, the submucous variety necessarily causes elongation of the uterine cavity, as indicated by the sound. In other varieties the canal may not be lengthened, but external movement of the tumor will be readily communicated to the sound. The history of ovarian tumors is usually well marked and distinct from that of fibroids. In the latter, if they are large, there is almost always a more or less abundant discharge, which the former lack. The latter usually have a long history, often without much constitutional disturbance; the former grow more rapidly, usually produce constitutional dis-

turbance, and especially a decided emaciation. These and other well-established points render the diagnosis of fibroid tumors of the uterus to a great degree a matter of precision.

The Operative Treatment of Fibro-myomata of the Uterus.—Mr. J. Knowsley Thornton (*Ibid.*) states that he proposes in this paper to place before the members of the British Medical Association (before whom the discussion took place) his experience in this matter and the views which have been founded upon it. He wisely remarks that he strongly objects to operative interference in ordinary cases. The classification which he adopts is the old-time one, which he thinks is both more correct and more useful than any other—viz.: 1, subperitoneal; 2, intramural; 3, submucous. Each of these varieties, with its concurrent conditions, is described. In removing tumors of the first class when pediculated, his plan is first to secure the pedicle by a ligature, which is tied around it. Then to thread an end of this same ligature through a needle, transfix the pedicle on the distal side of the first ligature, and subsequently tie in halves, or in smaller pieces, as may seem advisable. Hæmorrhage is effectually prevented, whether from slipping of a ligature or from a previous puncture of the pedicle. Sessile growths of this variety will justify operation when hæmorrhage, pain, and inconvenience from size and pressure are so annoying as to menace the person's life. The author has operated in three such cases. He includes fibro-cysts of the uterus in the same classification with ovarian tumors, and hence does not refer to them at length in this place. Under the second heading he remarks upon the serious and dangerous character of an operation for the removal of an intra-mural fibro-myoma involving, as they nearly always do, the opening of the uterine cavity. He thinks such an operation should never be done unless there is so much positive danger to the patient's life from the presence of the growth that it becomes imperative. Whenever the operation is done, the uterine cavity having been opened, all the cut surfaces should be brought outside of the peritonæum. He mentions as the two methods of accomplishing the latter end—first, the method by suture, in which the raw surfaces are turned into the uterine or cervical cavity; second, the method with the clamp or the *serre-naud*, in which the raw surfaces are brought out. He approves of the use of the *serre-naud* as the safer and better plan. Complete hysterectomy, he thinks, is safer and easier than partial hysterectomy. He refers to twelve cases of complete supra-vaginal hysterectomy in which he operated, removing the ovaries also in each case. Seven of the patients recovered and five died. Extra-peritoneal treatment has given the better results. Of the removal of the uterine appendages in the treatment of these growths he speaks in terms of the highest approbation. He has operated fifteen times without losing a patient, and in ten cases the tumors and menstruation have entirely disappeared. The other cases also promise well. His directions for removing these appendages are that the ligatures should be so applied as to completely cut off from the tumor the blood-supply from the enlarged ovarian, tubal, and other vessels. His opinion is that hysterectomy should be reserved for those cases which have passed beyond the period in which the uterine appendages can be removed. Hence the operation will have only a limited field.

Myomotomy.—Professor Schröder (*Ibid.*) also read a paper before the recent meeting of the British Medical Association. He remarks that the important points to be observed in the removal of large solid tumors of the uterus by laparotomy were: 1. A method of operating without great loss of blood. 2. A method of forming a good pedicle without danger from hæmorrhage. He considers that he has achieved these ends in the plan which he adopts and recommends. In cases of subserous myomata with narrow pedicles the treatment of the pedicle is

essentially the same as in ovariectomy, and the prognosis is equally good. If a subserous or interstitial fibroid of the fundus uteri extending upward is to be extirpated, the author recommends the following plan: A thin, solid India-rubber ligature is to be placed around the body of the uterus, after which the capsule may be incised and the tumor enucleated; or it may be removed by means of a V-incision at its base. As to the stump, the two surfaces may be stitched together, after being trimmed for that purpose, should it be necessary. Several rows of stitches unite the parts, the first row bringing the deepest parts together, and successive rows, as frequent as is required, being passed above this, until the last row unites the edges of the divided peritonæum. Only the sutures of the last row are visible, the others being cut short after they are passed. If the tumors are developed along the side of the body of the uterus, the difficulty in removing them is greater, but Schröder considers it best to save as much of the uterus and its appendages as possible. There being no pedicle to the tumor, it is necessary to make one out of the uterus. With suitable precautions, the ligaments on both sides are divided, the India-rubber ligature is placed around the uterus near the base of the tumor and the latter is then carefully cut away above the ligature. The surfaces of the stump are then brought together and covered with peritonæum in the manner which has been already described. In cases in which the tumor has developed at the lower part of the uterus, and has even extended into the cellular tissue of the pelvis, the difficulties are very great. The author treats the appendages as in the case last described, and then enucleates the tumor out of the pelvic cellular tissue. As to the cavity which remains, it is left alone in some cases; in others a drainage-tube is passed from it into the vagina, the wound toward the abdominal cavity being closed by bringing the incised edges of the peritonæum together. The indications for these operations are of a different nature from those which obtain in ovariectomy, and they should be urgent before an attempt is made to remove the tumor. The methods of operating will yet admit of improvement, and the author hopes that the time will come when the prognosis will not be much inferior to that which has been reached in ovariectomy. Schröder has operated on sixty-six patients with this kind of tumor; twenty of them have died, but of his last forty he has lost only nine, the improvement being due to the use of the India-rubber ligature, the method of suturing, and the plan of enucleation.

The Enucleation of Myomata.—Dr. R. Lomer ("Zeitschr. f. Geburtsh. u. Gynäkol.," ix, 2, 1883) observes that Schröder's success in myomectomy has rendered it desirable to compare the advantages of that operation by laparotomy with the method of enucleation *by the vagina*, and to fix the limits for the propriety and the desirability of each. The author thinks that myomectomy—that is, by laparotomy—will be much more extensively practiced in the future, as methods become tried and perfected. He lays great stress upon the extraordinary dangers which are sometimes encountered in the dilatation of the cervix, which may require repeated performance in those cases in which the tumor is removed *per vaginam*. The dilatation exposes the cervical mucous membrane to destructive changes which are apt to follow the hyperemia and ulceration to which it has been subjected, and is also very apt to be followed by fever. Enucleation by the vagina is, of course, useful in some cases, and was a last resort before the days of myomectomy. The prognosis in this latter operation, though it may have involved the opening of the uterine cavity from the peritoneal side, is not more unfavorable than obtains in complicated ovariectomy.

There are two classes of tumors which he thinks should be removed *per vaginam*: 1. Myomata of the cervix and the lips of the os. 2. Sub-mucous and intramural myomata which are

readily accessible from the vagina. If the cervix requires dilatation, especially if it is rather a long one, he does not favor enucleation by the vagina. He quotes Czerny, who advocates what he calls vaginal myomectomy for subserous myomata of the cervix and fibromata of the pelvic connective tissue. This operation may require an opening into the abdominal cavity through the vagina. A table of cases is added in which he gives the statistics of the vaginal operation as it has been performed in the last ten years.

Supra-vaginal Hysterectomy.—Dr. Keith ("Brit. Med. Jour.," Dec. 8, 1883) says that, since an ordinary uterine fibroid tumor has a limited life, it becomes a very important question to how far interference with its life is justifiable. The best results of the most skillful operators show a very high mortality, and Dr. Keith says he can not accept such a death-rate. Unless better results can be achieved, hysterectomy should be laid aside. He thinks that we still know little that is definite in regard to uterine fibroid tumors. There is great need of the details of a large number of operations, especially in cases which have been fatal. Dr. Keith removed his first fibroid tumor ten years ago, having erroneously diagnosed the condition as one of ovarian tumor. Two more were operated upon the following year, the condition being recognized in both cases, and the operations being done at the earnest solicitation of the patients on account of severe hemorrhage. Then a period of three years elapsed before any more operations were done. In all, Dr. Keith has operated twenty-five times, with only two deaths. Though he has discarded the spray, he makes this significant remark: "He is insane who does not now accept, *toto animo*, the antiseptic principle in surgery." The extra-peritoneal plan of treating the pedicle was adopted in most cases. The broad ligaments were sometimes returned into the cavity, and sometimes secured outside. The bladder was in several cases very large, sometimes rising as high as the umbilicus. The value of his advice to have the bladder full when undertaking an operation of this sort can be readily appreciated. In five of the cases the attempt was made to remove the ovaries, but it was found to be impossible. In all the cases in which recovery took place the health has been perfect ever since the operation. On account of the long period of convalescence when the extra-peritoneal plan of treatment is adopted, if for no other reason, he thinks the intra-peritoneal method should be perfected. Great success in performing hysterectomy must rest largely, as Schröder has said, upon the development of methods of operating. The author is not sure that the operation can be heartily advised unless we can get the mortality down to five per cent. in the bad cases.

Vaginal Hysterectomy for Cancer.—Professor Schröder's opening proposition in this paper (*Ibid.*, Sept. 15, 1883) was that the operative removal of cancer of the uterus was always indicated when it was believed that all the diseased tissues could be removed and no severe constitutional disease was present. In making an examination to decide as to the propriety of operative measures, the patient should be anesthetized, and in the dorsal position, and the examination be made very thoroughly by the bimanual method. It is very important, in deciding upon a case, to know how far the disease has extended along the mucous membrane of the uterine canal, and it is a fortunate fact that in the most common variety of cancer, the cauliflower excrescence, it is attacked late in the history of the disease. The order of development of the morbid process is, first, in the mucous membrane of the vagina; second, in the pelvic cellular tissue; third, in the tissue of the cervix; and, finally, in the cervical mucous membrane. The second form of cancer is less common than the one which has been described, and is the encephaloid. It ulcerates first in the interior of the cervix and cor-

pus, working outward in the reverse order of the cancrioid (cauliflower excrescence). Between these two forms is the scirrhus, or primary, cancer of the wall of the cervix. This form involves the body of the uterus and the pelvic cellular tissue at an early period, and last of all the cervical mucous membrane. Another and fourth form is that which first attacks the mucous membrane of the body of the uterus, and thence extends to the cervix. In operating for any of these varieties it may be necessary to remove, also, more or less of the vagina, but the expediency of such a procedure should first be fairly weighed. Cancroid of the cervix may be radically removed, also cancer of the wall of the cervix, always presupposing favorable conditions. If the mucous membrane of the cervix or of the body is invaded, the entire organ must be removed. In amputating the cervix, or performing what Schröder calls the supra-vaginal amputation, the cervix is divided on each side as high as the vaginal junction, being well drawn forward by a volsella in each lip. The vaginal mucous membrane is then divided by a circular incision at least one centimetre beyond the diseased tissue. The anterior lip is then cut off with scissors, care being taken to avoid the bladder, and also to cut into healthy tissue. The same procedure is adapted with the posterior lip. If arteries are divided, the bleeding is stopped by passing sutures around them. Deep sutures are passed to unite the vagina with the cervical mucous membrane, and thus cover the stump. Finally, the edges of the divided vaginal mucous membrane are brought together. If the entire uterus is to be removed, the first steps are the same as those in the operation already described, including the circular incision in the vaginal mucous membrane. Douglas's pouch is then opened by a transverse incision, the uterus tilted backward and pulled through the opening. This is followed by division of the peritonæum at the bottom of the vesico-uterine pouch, and this by ligation of the broad ligaments, either *en masse* or in two or three separate parts. The uterus is then cut away, and the ends of the broad ligaments are brought into the peritoneal wound, which is carefully closed with sutures. A drainage-tube also leads into the vagina, and around it is packed a tampon of salicylated cotton. The sutures are allowed to remain two weeks. In case the uterus is very large or the vagina narrow, it will be necessary to perform laparotomy, in which case Freund's operation, or some modification of it, must be done. Schröder has lost seven of the twenty-three patients upon whom he has performed this operation. With the supra-vaginal amputation he has lost eight out of sixty-four. He thinks the prognosis in these operations will improve as the methods are perfected, and that if only one in twenty is radically cured the result should be considered good, and a consolation for many unsuccessful cases.

An interesting discussion followed the reading of this paper, which was participated in by Sir Spencer Wells, Mr. Rogers, and Mr. Thornton. Mr. Wells read a letter from Olshausen, in which he spoke of a modification in the operation for removal of the uterus, which consisted in deterring the ligation of the broad ligaments until late in the operation, and then applying elastic ligatures by means of a bent aneurysm-needle. A long stump, with plenty of cellular tissue, was thought to be desirable to prevent retraction and slipping of the ligatures. During the operation the parts should be irrigated with a two-per-cent. solution of carbolic acid, and after the removal of the uterus the pouch of Douglas should be washed out with a four-per-cent. solution of boric acid. A drainage-tube should be passed through the peritoneal wound into the vagina, the edges of the divided peritonæum be brought together with sutures, and the vagina tamponed loosely with iodoform gauze. The gauze and drainage-tube should be removed between the fourth and the eighth days, and the elastic ligatures after two or three weeks.

Of the twenty-eight cases in which Olshausen had attempted the operation, three were incomplete; of the others, seven proved fatal, and in several others there had been a recurrence of the disease. Rogers, of London, remarked that he had not yet lost all hope of success in the operation for extirpation of the cancerous uterus. As to partial removal of the organ, he had had good success, especially when he followed up the cutting operation with applications of chloride of zinc and bromine. Thornton expressed great disappointment at the results which had been achieved by Schröder and Olshausen, and did not believe in the hopefulness of the operation which required extirpation of the entire uterus. He thought that both the vaginal and the abdominal operations would soon drop out of surgical practice.

The Palliative Treatment of Cancer of the Uterus.—Dr. J. E. Burton (*Ibid.*) thinks that we are too apt to be discouraged in treating this disease, and to make no attempt to do anything when the disease is in an advanced stage. Four measures can always be taken, with more or less success: 1. We can attempt to bring about a more healthy action in the parts. 2. We can relieve pain. 3. We can moderate discharges, especially those of blood. 4. We can remove the factor of the discharges. He suggests that the progress of a neoplasm may be checked, at least for a time, by exciting an inflammation which shall affect its immediate surroundings. Such a cordon of inflammation might be excited by the action of iodine or iodized phenol. He quotes Duplony as considering that concentrated acetic acid is the most satisfactory substance for such a purpose. Gallard is much in favor of the actual cautery, which he thinks might be used freely as often as once in three weeks. Of other caustic agents, nitric acid, acid nitrate of mercury, bromine, sulphuric acid, bichromate of potassium, nitrate of lead, chlorate of potassium, and resorcin, all have been used by the author and are of benefit in certain cases. Before caustics are applied to an exuberantly granulating surface, the granulations should be scraped away as thoroughly as possible. For the relief of pain nothing better than opium, in some form, by the rectum, can be given. To diminish the vaginal discharge, any reliable astringent injection may be used. Subcutaneous injections of ergotin will have a good effect in controlling hæmorrhage. The factor which is so offensive can be controlled by vaginal suppositories of iodoform, used night and morning. The author has also found that Chian turpentine lessens the quantity of the discharges and the tendency to hæmorrhage—hence it is not valueless. He thinks a spare diet is to be preferred when it is possible. In the discussion, several well-authenticated cases of cure of uterine cancer were related.

Cancer of the Neck of the Uterus and its Treatment.—Dr. A. Wynn Williams (*Ibid.*) stated that he thought the difference, if any, between epithelioma and medullary tumor of the neck of the uterus depended solely upon the texture from which each originated, the medullary growth starting from the interior, the epithelioma, or cauliflower growth, from the exterior of the cervix. He would lay stress upon the premonitory subjective symptoms of cancerous disease—viz., continuous pains in the back, extending down the thighs, especially the left one, irregular and profuse uterine discharges, watery, sanious discharges from the vagina, etc. Then the patient should be carefully examined and closely watched. If the mucous membrane of the vagina had not yet been invaded, and the other neighboring structures (glands and cellular tissue) were still free, the diseased organ might be taken away, the sooner the better. If the disease is epitheliomatous, the author prefers the *écraseur* for removing it, and goes as near Douglas's pouch as possible. The operation is performed with the patient in the dorsal position. Bleeding points are touched with the cautery, and the same in-

strument may be useful in destroying diseased surfaces which were not reached by the *éraseur*. It is also applied to the entire surface of the wound, after which the vagina is tamponed with cotton, of which the portion next the wounded surface is treated with a solution of perchloride of iron in glycerin; and finally a T-bandage is adjusted. After two days the tampon is removed, and the vagina is syringed out four times daily with a weak solution of iodine in water until the slough produced by the cautery has come away. Next a plug of cotton, which has been dipped in a solution consisting of one part of bromine and three of spirit of wine, is carefully applied to the raw surface, the surrounding tissues being protected by cotton which has been soaked in solution of bicarbonate of sodium. The slough produced by this application comes away in a week or ten days, and the operation is to be repeated if any evidences of the disease remain. If the disease is of the medullary character, its true nature may be overlooked until ulceration involving a large portion of the cervix has occurred. Of course, the cervix should be amputated as soon and as thoroughly as possible (supposing always that the surrounding tissues are not too much involved), and the bromine applications used, as already described. The scirrhus form of cancer is not common in the cervix uteri. When it does occur, the author's recommendation is to amputate the cervix or to inject bromine into it. The treatment following amputation should be the same as in the two other varieties.

The Diagnosis and Treatment of Subperitoneal Cysts of the Ovary.—Dr. T. A. McGraw ("Am. Jour. of Obstet.," Oct., 1883) remarks that the literature of this subject is very meager, consisting mostly of reports of isolated cases. Such a case occurred in his experience in the person of a primiparous widow twenty-four years of age. He was called to see her during menstruation, and found symptoms of an attack of acute peritonitis. There was also a tumor, of an elastic character, in the lower part of the pelvis, which could be clearly outlined. It had been developing for a year, and was apparently firmly adherent to the pelvis. A short time previous to the operation which was determined upon the tumor was tapped, and inflammation followed. At the operation the cyst was found covered entirely with peritonæum. There were many strong adhesions, some of which extended to the rectum. In separating the latter, the rectum was wounded, but the wound was carefully closed. The patient lived only twenty-four hours after the operation, and there was no autopsy. Examination of the specimen showed that the cyst was entirely subperitoneal, having developed from an ovary between the layers of the broad ligament. As to the literature of this condition, Freund and Beigel consider that these growths follow faulty development of the ovary. Olshausen also has seen several interesting cases, and he is opposed to operation when such a condition can be clearly diagnosed. The peculiar difficulties which one is liable to meet with, and which require special treatment in case of operative interference, convince the author that intra-ligamentous tumors should be classed by themselves, and be treated according to the conditions which they present.

Miscellany.

THERAPEUTICAL NOTES.

Static Electricity as a Preventive of Cholera.—In a recent number of the "Progrès médical," M. Romain Vigoroux speculates as follows: "Among the innumerable preservatives against cholera which are being

proposed daily, some are manifestly insignificant; others may end in weakening the system, and thus defeat their object; but still others, more rational, consist in the employment of antiseptics. But antiseptics are numerous; in general, each of them acts only upon a particular category of inferior organisms. How, then, shall we make a choice, since we know neither the agent of transmission of cholera nor the conditions of its existence? In this state of uncertainty, it is logical to seek for an antiseptic with the most extensive sphere of action, and one which exerts its destructive effect upon parasitic elements indiscriminately. These things considered, ozone should be placed in the front rank. Moreover, it has already attracted the attention of physicians. In England, particularly, it was proposed, about twelve years ago, to make cholera patients breathe ozone. M. Pasteur's learned collaborator, M. Duclaux, thus expresses himself on this point:

"The experiments of Boillot, of Angus Smith, and of Chappuis bear testimony that, in certain cases, ozone may be a very active disinfecting agent. M. Chappuis submitted wads of cotton, charged with dust collected from the air, to the action of a current of ozone, and found that they could then be sown in a nutritive solution without growing. So far as I know, the amounts of ozone necessary to produce disinfection have never been measured experimentally, but without doubt they may be very small; and, if arrangements are made to make the disinfection continuous—if, consequently, the element of time is availed of—there is ground to hope for good results.

"As a matter of fact, it is comparatively easy to charge air with appreciable amounts of ozone. There are many ozonizers, some of which are very efficient, but the most practicable measure is founded on the use of essences. Schönbein was the first to observe that certain essential oils disengage ozone during the process of their oxidation. Angus Smith made a classification of the more common of the volatile oils according to the amounts of ozone they thus disengage, taking for his guide the tints imparted to ozonometric paper. He placed essence of orange-peel in the first rank, then essence of turpentine, then those of juniper, of cumin, and of lavender. On account of its cheapness, oil of turpentine is the most available, and a current of air circulating over large-meshed fabrics saturated with the essence would deserve study as a disinfecting agent."

"Two chief things will be remarked in this quotation: In the first place, the result of M. Chappuis's experiments, which prove that ozone neutralizes *all* the germs contained in the atmosphere; then the known fact that the essences owe their incontestable efficiency to the production of a certain quantity of ozone. In this connection it can not be denied that, as a means of disengaging ozone for the disinfecting of houses, the exposure of essential oils to the open air is within the reach of all; but, if it is a question of more localized applications, and where the quantity of the gas must be more considerable, it is quite necessary to resort to the ozonizing apparatuses, such as those of Houreaux, Siemens, A. Thénard, and Berthelot. All these apparatuses are founded on the property possessed by the electric discharge of partially transforming oxygen into its isomer. Let us add two important details: On the one hand, the obscure discharge is much more active than the electric spark, and, on the other hand, the mixture of certain gases with the oxygen favors its transformation. Of all gases, nitrogen is the most efficient in this respect. The production ought, therefore, to be very easily brought about by the obscure discharge in the air.

"This being the case, it will be seen that electrization with the electrical machine that is now getting to be used in electro-therapeutics furnishes conditions in the highest degree favorable to ozonization. To convince one's self of this, there is no occasion to have recourse to ozonometric paper. So soon as the machine is set in operation, ozone announces its presence by its characteristic odor. This odor becomes much more marked if, without provoking a spark, a metallic exciter with a pointed end, or a blunt shaft of wood, is directed toward the patient seated on the isolating stool. Some patients declare that, after having been thus electrified, the smell of ozone clings to their clothing and to their skin for several hours, and even until the following day. In such a case, it will be seen, the ozone is not merely diffused through the air; it is produced on the surface of the body which it impregnates—that is to say, at the very limit which the morbid agent must pass in order to become dangerous.

"Given, then, the preventive properties of ozone, is it not evident that the surest way of making use of them is by static electrization? We are thus led to consider this electrization as one of the most rational among the preventives of cholera. We have the less hesitation in selecting it, because, besides its prophylactic action, it presents, contrary to most of the means that have been recommended, the positive advantage of improving nutrition, and thus increasing the vital resistance. The remarkable accelerating influence of static electricity on the chemical phenomena of nutrition explains its utility in numerous morbid states connected with a retardation of this function.

"Not to speak of clinical observations, we have observed a fact which well shows the energy of this action of electricity on the intimate phenomena of nutrition: the simple electric bath, i. e., a stay of a few minutes on the isolating stool, suffices to raise the temperature from 0.8° to 0.7° C., according to the peculiarities of the subject. This is not the place to insist upon this argument, which we propose to develop in a special work. We may now formulate the following conclusion:

"According to data generally admitted in regard to the prophylaxis of cholera, static electrization practiced daily is the means of which the efficacy is the most probable. It acts at the same time by producing an antiseptic *par excellence*, ozone, and by stimulating all the functions of the organism, and especially that of nutrition."

Peptonized Fibrin as a Food for the Insane.—At a recent meeting of the *Société de Biologie*, a report of which we find in the same journal, M. Grehant gave the following formula of a "peptone of fibrin" which he had used in the alimentation of the insane:

Commercial pepsin.....	2 grammes;
Fibrin (from the slaughter-houses).....	100 "
Water.....	1,000 "
Hydrochloric acid.....	1 cubic centimetre.

M. Bouchereau had fed insane patients with this preparation, and had found improvement at the end of a month or six weeks. He proposed to continue his experiments. He had not ascertained whether or not there had been any increase in the excretion of urea. The "*péripéptone*" had always been given by the mouth, and never as an enema. M. Henninger had experimented with peptones in the form of enema in one patient, without provoking proctitis, and the excretion of urea had been increased to the extent of four or five grammes in the twenty-four hours. M. Quinquand had tried the "*fibri-peptone*" with his patients, giving two hundred grammes daily, in thin bouillon. There had always been an increase of weight, together with a heightened excretion of urea and carbonic acid.

A Classification of Antiseptics has been made by Dr. Miquel ("*Annuaire météorologique de Montsouris*," 1884; "*Progrès médical*," July 10, 1884), according to their power of destroying the micro-organisms in beef-broth. He makes three classes, as follows:

I. *Substances "eminently" antiseptic*: 1° Biniodide of mercury; 2° iodide of silver; 3° oxygenized water; 4° bichloride of mercury; 5° nitrate of silver.

II. *Substances "very highly" antiseptic*: 7° Chromic acid; 8° chlorine; 9° iodine; 12° hydrocyanic acid; 14° bromine; 15° iodoform; 18° chloroform; 19° sulphate of copper.

III. *Substances "highly" antiseptic*: 20° Salicylic acid; 21° benzoic acid; 22° cyanide of potassium; 23° picric acid; 29° chloride of zinc; 30° thymol; 43° phenic acid; 44° permanganate of potassium; 49° tannin; 51° tartaric acid; 52° citric acid, arsenious acid, boric acid, hydrate of chloral, sulphate of iron, ordinary alcohol, and hyposulphite of sodium.

The author of the abstract in the "*Progrès médical*" remarks that the results on which M. Miquel's classification is based should not be held to apply to the lower organisms in general, but only to those that were propagated in beef-broth.

Orthoxysulphite of Phenyl.—In the "*Journal*" for July 19th we gave a brief note in regard to this new antiseptic. In a summary recently published in the "*Pharmaceutische Rundschau*" some further facts of interest are stated. Besides the name given in the heading of this paragraph, the substance is also called orthoxyphenyl sulphurous acid (*acidum orthoxyphenylsulphurosum*), and the term "aseptol" has

been applied to it. Its molecular structure, as compared with that of salicylic acid, is shown in the following formulae:

Orthoxysulphite of phenyl is a viscid, slightly reddish liquid, of the specific gravity of 1.450, with an odor somewhat like that of carbolic acid, but feebleness, and is said to be miscible with water in all proportions. Its antiseptic and anti-fermentative properties are described as being fully equal to those of carbolic acid. For internal use, the dose ranges between that of carbolic acid and that of salicylic acid, and, used within that range, it has not thus far given rise to toxic symptoms. For lotions, injections, etc., it is serviceable dissolved in ordinary water in the proportion of 1 to 1,000.

The Action of Iodide of Methylene, according to recent investigations by E. Schwerin ("*Centralbl. f. d. med. Wissen.*," 1884, 9, 10; "*Deutsche Med.-Zeitung*," 1884, 57), like that of the analogous chlorinated methane product, bichloride of methylene, is stupefying, anæsthetic, and hypnotic. After a brief period of excitement, both cold-blooded and warm-blooded animals, when exposed to the action of its vapor, become somnolent, the frequency of their respiration falls, their pupils become contracted, and they are deeply narcotized, but the reflex irritability is not abolished. The deep sleep lasts for two hours. The ingestion of the substance into the stomach causes either a soporose or a cataleptic condition. Most of the animals experimented upon died within a few hours after the sleep had passed off. The author considers that the hypnotic effect is due to the organic constituents of the compound, while the fatal result is caused by the iodine, which may be detected in the brain.

The Action of Hydrate of Chloral on the Cerebral Circulation.—In an article on the action of various medicines on the intra-cranial circulation, Curci ("*Sperimentale*," "*Deutsche Med.-Zeitung*") infers that chloral causes cerebral anæmia, for the bulk of the brain is decidedly diminished during the sleep that the drug produces. Although at first the pulsations of the brain are more marked than normal, they subsequently become smaller and more frequent.

The Value of Phosphorus in the Treatment of Rickets.—Soltmann ("*Breslauer ärztl. Zeitschr.*," "*Deutsche Med.-Zeitung*") declares himself in enthusiastic accord with Kassowitz in regard to the great value of phosphorus in the treatment of rickets, but his paper is theoretical in its scope, as he reserves his facts for a subsequent communication. *Per contra*, Schwachten, who made the abstract of Soltmann's article for the "*Deutsche Medizinisch-Zeitung*," declares that his own experience does not support the views of that author and Kassowitz, and he quotes Weiss, of Prague, to the same purpose.

The Supra-frontal Sulcus.—The "*Gazzetta Medica Italiana-Lombardia*" gives a summary of a description, by Professor G. Zoja ("*Archivio Italiano per le Mal. Nerv.*," etc., iv, 1884), of a sulcus which that author has met with in rather more than sixteen per cent. of the skulls that he has examined, and which he thinks has not hitherto been sufficiently known. He thinks it is probably due to the pulsations of the external frontal artery. It is found oftener in women than in men, oftener on one side than on both, oftener on the left side than on the right, and appears common to both ancient and modern crania and to all races.

Personal Precautions against Cholera, as understood in the last century, are summarized in the following quatrain, quoted in a recent lecture by Professor Castan, of Montpellier, a report of which we find in the "*Gazette hebdomadaire des sciences médicales de Montpellier*":

*Tiens tes pattes en chaudi,
Tiens rides tes banyans,
Ne vois pas Marguérîte;
Du choléra tu seras quitte.*

Italian Medical Journals.—According to the "*Raccoglitore Medico*," quoted in the "*Deutsche Medizinisch-Zeitung*," there are fifty-one medical journals published in Italy—seven in Milan, two in Pavia, one in Padua, one in Venice, five in Turin, two in Genoa, two in Piacenza, one in Modena, one in Reggio Emilia, two in Bologna, three in Florence, one in Forlì, one in Pisa, four in Rome, ten in Naples, four in Palermo, one in Messina, one in Ariccia, one in Bari, and one in Siena.

Lectures and Addresses.

ON THE DEVELOPMENT OF PHYSIOLOGICAL CHEMISTRY AND ITS SIGNIFICANCE FOR MEDICINE:

AN ADDRESS DELIVERED AT THE CELEBRATION OF THE
OPENING OF THE NEW INSTITUTE FOR PHYSIO-
LOGICAL CHEMISTRY OF THE IMPERIAL
UNIVERSITY OF STRASSBURG,
FEBRUARY 18, 1884.*

By PROFESSOR FELIX HOPPE-SEYLER.

Translated by T. WESLEY MILLS, M. A., M. D.,

DEMONSTRATOR OF PHYSIOLOGY, MC GILL UNIVERSITY, MONTREAL, CANADA.

THE mere opening of another large and elegant structure in connection with Strassburg University can in itself have no great interest, as of these there are already so many. This is, however, the first building erected by a German university for the investigation and teaching of the science of physiological chemistry. Allow me, then, to give the objects for which this building has been erected, afterward a short sketch of the history of physiological chemistry, and finally to indicate what the plan and arrangements of the structure itself are. For hundreds of years have able physicians zealously interested themselves with the chemical investigation of the composition of the organs of the human body and its life-processes, the knowledge of which seemed of great value in determining the causes, course, and treatment of disease. Previous to the discovery of oxygen by Priestley and Scheele, and to the time when the penetrating Lavoisier, with experiments of previously unknown accuracy, gave chemistry a surer foundation, very little came out of this investigation. Especially such discoveries as that of the composition of water, of carbon dioxide, and of other important compounds of a simple kind, are to be noted in this connection. It would be wholly wrong to suppose that the brilliant discoveries of the last quarter of the eighteenth century were the results of this period alone; in fact, the way had been already prepared, and other important discoveries made. Among others, the numerous and valuable discoveries of Scheele, the accurate measurings and weighings of Lavoisier, and his proposed antiphlogistic theory, gave alike an invaluable foundation for the science of chemistry, and also a point of observation for its organization.

Already these beginnings of scientific chemistry had shown themselves fruitful for physiology. The investigations of Scheele, Lavoisier, and Van Ingen-Housz on the respiration of animals, sprouting seeds, green plants, etc.,

gave physiology a deep insight into the chemical relations of organisms to the surrounding atmosphere. Scientific chemistry and physiological chemistry have here alike a common origin. But, though by Scheele and many others, especially French chemists, many important substances of the animal and plant world were brought to light, yet organic chemistry, and with it physiology, remained far in the rear of the advancing knowledge of inorganic substances. The limitation of the attention to the inorganic part of chemistry was authorized, inasmuch as it was to furnish that knowledge which for all time would remain a certain basis.

In the second decade of our century chemistry again began to grow and to be the food of physiology. Organic chemistry remained as yet almost identical with animal and plant chemistry. The labors of Chevreul on the fats, of Prout, Tiedemann, and Gmelin on digestion, of Prevost and Dumas on the composition of the blood and the formation of urea, which belong to this period, wonderfully enriched our knowledge of life-processes. In 1828 Wöhler accomplished the synthetic formation of urea from cyanic acid, previously discovered by him, and ammonia. *For the first time, here was a substance, which had been previously known only as a normal product of the processes of life, formed out of its inorganic elements.*

Soon after, Berzelius and Liebig greatly increased the existing knowledge of organic substances. A theoretical war of thirty years' duration sprang up, but it proved fruitful in investigation, especially of the organic realm. Organic synthesis, together with the explanation of theoretical points; the rearrangement of groups on physical and chemical grounds; the mechanical theory of gases and vapors, which first gave a foundation for the estimation of the relative weight of molecules and the number of the atoms contained therein; the relation of atoms in molecules; and the theory of organic chemistry in its essentials, founded on the affinities of the carbon atoms—offering many points difficult of solution and still controverted—all was the fruit of this period.

It would be difficult to enumerate all the chemists to whom this progress was due, but the names of Laurent and Kekulé are the foremost. It could justly be said, as Lothar Meyer said in 1864, that already for a long period the controversy over the systematic arrangement of chemistry had ended. In consequence of this controversy, however, physiological chemistry had in general been overlooked, though Liebig was not one of those who neglected it. From 1830 till old age, though engaged in almost every controversy of the time, he labored to advance it. He had himself worked out excellent methods of determination, and had made investigations into the constitution of flesh; and his keen insight gave to his pupils correct methods of research for the accomplishment of decided results. The pregnant ideas of his writings prompted numerous valuable researches. His investigations of the relation of food to life-processes and to muscle-work are especially noteworthy. They have directly or indirectly led to researches of wide application to agriculture, medicine, and hygiene, and especially in the last ten years. Though the hypothesis relating

* Any views of Professor Hoppe-Seyler's on the relations of physiological chemistry must attract attention in every quarter of the world. This translation has been undertaken in the hope of bringing the matter of his recent address within reach of a larger number. While the first few pages have been rendered freely and somewhat condensed, a closely literal translation has been given of the remaining ones, owing to the importance, originality, and extreme interest, alike to biologists, chemists, and physicians, of the opinions they contain. The admiration and gratitude of the pupil have rendered the task pleasant.—THE TRANSLATOR.

to the formation of fat within the organs from albuminous matters has proved erroneous, the results of the work of this period in their practical worth remain uncontroverted.

Important advances were made in other directions. Ferments acting on diastase and starch were discovered in the saliva, and afterward in the pancreatic secretion. Schwann extracted pepsin from the mucous membrane of the dead stomach with dilute hydrochloric acid; and the action of this artificial digestive fluid on albumin was ascertained. C. Bernard subsequently discovered the emulsifying action of the pancreatic juice on fat, and the remarkable formation and changes of carbohydrates in the animal body, especially in the liver, as dependent on the method of feeding; and various other influences were recognized. The composition and conditions of secretion of the various digestive fluids in their main outlines were ascertained. With new and excellent methods and apparatus, and by very numerous and varied researches, was the interchange of gases in the respiration of animals of different classes, under varying conditions of nutrition and many other circumstances, investigated by Regnault and Reiset.

New substances were found in the organs of men and animals in health and disease. With the noted researches of Liebig on flesh may be ranked the labors of Strecker on the biliary acids; of Strecker and Scherer on xanthin, hypoxanthin, and guanin; of Frerichs and Städeler on leucin, tyrosin, etc.

The investigation of the composition of the blood in health and disease was at this period the subject of numerous researches in Germany and France. C. Schmidt's research "On the Characteristics of Epidemic Cholera" deserves special mention. Nor have these researches remained without fruit, though the over-zealous opposition of the Prague-Vienna school against bloodletting had an injurious influence, which has not yet been wholly removed.

Of enormous value for physiology was the discovery of Magnus that from the blood, when subjected to a good vacuum, together with carbon dioxide and a little nitrogen, oxygen also was given off, and, in fact, more from arterial than from venous blood. Few then anticipated, with Johannes Müller, the enormous consequences of Magnus's discovery, and, in fact, able chemists were at once ready to controvert it.

The researches of Schönbein on the peculiarities of oxygen in different conditions; the formation of ozone, hydrogen superoxide, etc., did not receive generally the attention they deserved. Liebig fully understood their value.

To the casual observer, looking from a distance, nothing very striking in the development of physiological chemistry may seem to have occurred in the last twenty or twenty-five years. It has, however, been in good fortune. The general advance of chemistry, especially since 1850, and in particular the improved methods of gas analysis due to Bunsen—the improvement in apparatus, spectrum analysis, etc.—have all contributed to the advance of physiological chemistry.

The publication in the second half of the fifth decade of this century of Virchow's "Cellular Pathology," together with the researches of Max Schultze on the structure of animal cells, which soon followed, though of no direct

bearing on physiological chemistry, yet afforded new points of view. The researches of Pasteur and his pupils and opponents, from the beginning of the sixth decade onward, have had a notable influence on physiological chemistry.

These researches, though as yet abounding in obscurities and uncertainties, have still given results of the highest value for the technique and for medicine.

The treatment of wounds to the exclusion of infection, the relation of sepsis to operative surgery, and the discovery of micro-organisms of definite character in the blood in certain diseases, are of a value well recognized. There is no limited region of natural science which at the present time attracts zealous investigators in so great numbers as the microscopic determination of the conditions of life and propagation of these micro-organisms. Botanists, chemists, physiologists, normal and pathological anatomists, surgeons, pathologists, and hygienists contend in the race in this realm of investigation.

Difficult is it to separate the chaff from the wheat. Owing to the extreme minuteness of these organisms, their anatomical investigation and certain separation are very difficult. But the difficulty is greatly increased, owing to the power many of them possess, according to the conditions under which they are found, of developing into entirely different forms, and at the same time occasioning entirely different chemical processes, according as the chemical and physical conditions surrounding them vary.

Physiological chemistry partakes of a far greater share of difficulty than the microscopic investigation, which, apart from the method, now much used, of impregnation with coloring matters (which also leads to manifold deception), without simultaneous chemical investigation with sufficient certainty, can not make great advances. This investigation, as I shall soon have occasion to illustrate, brings great gain to physiology itself.

I must abstain from giving you a complete outline of the advances physiological chemistry has made with reference to the composition of the organs and fluids of the human body, and the processes taking place in them, effected in the last two decades. Allow me to sketch the manner in which, in the most recent period, the science has advanced.

With great diligence, and not without success, the processes of the digestion of all the most important constituents of food in the alimentary canal, with the sole exception of the part played by the bile (which, indeed, does not seem essential, and which is wanting in invertebrates), have been studied, and it has been ascertained that these processes in all their phases may be carried on outside the organism, and the products of their action isolated and investigated. Medicine and hygiene in this case, as well as physiology, have become possessed of treasures of knowledge the practical value of which already abundantly appears, but *far short of the extent to which it must appear in the diagnosis and treatment of diseases of the alimentary tract especially.*

Our knowledge of the composition of the blood and its changes under the influence of certain physiological processes has been essentially advanced in the line referred to; and the chemical functions of the red corpuscles in respira-

tion, especially the influence of the coloring matter in reference to the absorption of oxygen from the air in the lungs, its transportation to the cells of the organs, and their proximate causes, are so well known that, in a given case, it is merely a question of reckoning to determine the total quantity of oxygen appropriated in a given period by definite extents of surface, etc.

With reference to the life-processes within organs, such as muscles and glands, the passage of the free, indifferent oxygen of the air into these organs has been demonstrated with certainty. The chemical structure of numerous substances already known which arise in the organism has been determined, and their formation by synthesis accomplished; others have been discovered and to some extent artificially formed, and many general laws in regard to their formation and behavior with reference to the peculiarities of their chemical structure discovered, and, above all, the interesting formation and processes of change of the aromatic bodies in their characteristic combinations with sulphuric acid, glycocholl, glycuronic acid, and cystin.

By the last-mentioned investigation have the methods and results of the new theoretical chemistry become of great value for physiology, while interesting new material for chemistry has appeared.

Even with more and more clearness during the course of these investigations has the fact become recognized that the substances which form the organs, out of which they build themselves up and are regenerated, belong to a class which may be included under the term *anhydrides*, and which have the common property that, under treatment with alkalis and acids, many of them also, through fermentations, can be changed or split up with the addition of the elements of water, thereby, as it is said, becoming hydrates.

These anhydrides show mostly in striking chemical affinities, swell in water or dissolve generally with difficulty in it; they withstand the action of the atmospheric oxygen, and, so far as it can yet be made out, have very large molecules.

Animals and plants are, as regards these substances in general, not different, though certain substances, as albuminous matters, fats, and inosit, appear in both; others, as cellulose, starch, cane-sugar, tannic acid, and malic acid, only in plants; others, again, as glycogen, less in plants than in animals; finally, certain substances, as gelatin, urea, and creatin, are formed only in animals.

The line of demarkation which it was once thought could be drawn in regard to chemical structure and life-processes between plants and animals has been, in consequence of recent investigations, more and more obliterated.

The discovery of inosit, glycogen, and allantoin in plants; the establishment of closer relations between the caffeine and theobromine of plants and the xanthin and guanin of animals, especially the presence, without exception, of globulin substance, lecithin, cholesterolin, nuclein, and potassium in all cells formed under normal or pathological conditions so far as yet investigated, whether in man or in the highest or lowest animals and plants—all these considerations must bring us to the conviction that *definite fundamental chemical formations and changes are common to all living beings, and that the life-processes common to them all,*

especially their growth through formation of their own substance and their propagation without limit under conditions peculiar to them, must be formed in the presence of those chemical constituents; that also in the further processes of change, often appearing so different in the different classes, orders, and families of animals and plants, many processes can take place according to a conformable fundamental type; and that finally in the life-processes of man these parallels are again found, whose simplest manifestation we, perhaps, follow with the least difficulty in the lowest organisms.

We are thus brought to a definite unity in the original chemical structure and processes of living existence, a point which the microscopico-anatomical investigation of the morphological development has already reached. The chemical characters are, however, much more within our ken than the microscopic, since the latter take cognizance of the simplest forms of existence, as plastic, variable, or irregularly formed little masses.

When the chemical components of the cells or the protoplasm, or any formed organ of animals or plants, is spoken of, it is, of course, to be observed that we yet have no right to speak of the constituents of living cells, but only of the products of their chemical decomposition. A series of observations of different kinds points in the direction of the conclusion that the change which simple protoplasm, as well as complicated organs, undergoes on the entrance into the death state, arises from the chemical addition of water. If the water essential for all life-processes be removed, life is indeed suspended, but death does not, in consequence of this alone, follow. Plants, insects, amphibians (e.g., tritons), and frogs can for a long period remain hard frozen; their life is thereby fully suspended; after being slowly thawed out, the organs take on again all their life-functions. The noses, ears, hands, and feet of men act similarly when frozen by a degree of cold not too intense. But such frozen organs die at once if thawed out too quickly, inasmuch as the melting ice-crystals injure the cells in juxtaposition to them. Carefully dried seeds of plants—e.g., peas—can be kept heated for hours at 100° C. without their vitality disappearing. They sprout, after cooling, when placed in water or moist earth just as quickly as undried and unheated peas, and develop to perfectly healthy plants. If the seeds are not carefully and fully dried before the heating, they perish under 60° C. If now, from these and many other experiences, it is to be concluded that the death of protoplasm arises from assumption of water, then must it be assumed that the *forms of living protoplasm conduct themselves in respect to the substances found in the dead forms of the same as anhydrides do to their hydrides or decomposition products*, unless some further insight into this matter is forthcoming.

(To be concluded.)

Medical Life Peers.—"The Lancet" (July 12, 1884) says: We understand that Dr. Lyons, M.P., has given notice of an important amendment to be inserted in the Medical Act Amendment Bill, to the effect that two physicians of over twenty years' standing should be made life peers and act as lord justices of appeal in medico-legal trials. Such appointments have been urged by Sir Spencer Wells, Dr. Theodore Williams, and others, and will, if made, considerably strengthen the hands of justice.

Original Communications.

A CRITICISM OF

DR. FORMAD'S PRINTED STATEMENTS
AND CONCLUSIONS CONCERNING THE
ÆTIOLOGY OF TUBERCULOSIS.

By EDWARD O. SHAKESPEARE, A. M., M. D.,

PHILADELPHIA,

OPHTHALMIC SURGEON AND PATHOLOGIST TO THE PHILADELPHIA (BLOCKLEY)
HOSPITAL, ETC.

(Concluded from page 146.)

ANOTHER specimen of our author's peculiar method of ratiocination frequently exemplified in his consideration of the ætiology of tuberculosis is subjoined.

After arguing against the conclusions of Tappeiner by misrepresenting his experiments, as has been already shown, our author proceeds to prove that neither general tuberculosis nor pulmonary tuberculosis can be produced in the dog by inhalation either of indifferent matter or of tuberculous matter, and to declare that his own experiments, which he *promises* shall be forthcoming at some future time, and "the experiments of Schottelius, Wargunin and Rajewsky, Weichselbaum, and others, make Tappeiner's assertions perfectly untenable."

As to the results of the author's own experiments upon this point, he will perhaps excuse us from attempting to estimate their weight in the settlement of this question until we are fully apprised of their character and details. We may be allowed, however, to offer the hope that, ere the future time of these promised experiments has arrived, the author will have found "the pivot of the question" and have learned "what to call a tubercle or a tubercular lesion."

As to the results of the other experimenters, they are, it is to be presumed, relied upon by the author to show that in dogs the products of the inhalations do not extend beyond the lungs and are nothing but nodules, more or less diffuse, of broncho-pneumonia. Very good. Now let us arrest ourselves for a moment and turn back again, to learn, if possible, what our author means by broncho-pneumonia.

On page 344 (*l. c.*, Feb. 9, 1884, par. 2, right column) occurs the following sentence: "I class myself with those who regard all forms of pulmonary phthisis as tubercular." The succeeding paragraph commences with these words: "The lesions that are known as catarrhal pneumonia, *broncho-pneumonia*, pneumonic phthisis, cheesy pneumonia, tubercular phthisis, and fibroid phthisis, are all manifestations of the one disease."

This is the way in which the products of inhalation which Tappeiner has obtained are shown to be simple broncho-pneumonia and non-tubercular in their nature. In this manner would the conclusion of Tappeiner, that tuberculosis can be communicated even to the highly resistant dog, be "proved a fiction" and declared untenable by our author. It may be set down to his credit, however, that while he contests the conclusions of Tappeiner concerning dogs he generously admits "that the pulmonary tubercu-

losis may occasionally be produced in rabbits by these means" (Par. 2, right column, page 489, "Phila. Med. Times," April 5.)

In disposing of the fourth point, *d*, we might urge that all there is now left of it is that non-tubercular substances may sometimes produce, by inhalation, broncho-pneumonic foci in the dog, and leave this question just there until our author has learned some method by which he can satisfy even himself as to whether his broncho-pneumonic foci are tubercular or not, and as to whether, by some fixed anatomical criterion, he knows how to distinguish between these pneumonic foci and true tubercles.

But the citation by our author of the experiments of Weichselbaum, as in harmony with those of Schottelius and as a part of "the proof" which makes "Tappeiner's assertions perfectly untenable," gives occasion for their recital here in order to show that Weichselbaum also has been characteristically misrepresented.

As for Weichselbaum's own *deductions* from his experiments, the following shows not only that he is by no means in accord with Schottelius (who maintains that there is no difference between tuberculous matter and any indifferent material in the effect produced in dogs by inhalation), but that, on the contrary, Weichselbaum is rather more in agreement with Tappeiner.

Weichselbaum ("Inhalationstuberculose," "Centralblatt," xix, 1882, p. 340) says: "From the foregoing experiments it follows that not only tuberculous sputum, but certain other organic substances, possess the faculty of exciting tubercle-like nodules, but that, in spite of this, contrary to the results of the experiments of Schottelius, a difference in the effect of the above-mentioned substances must be admitted—namely, in tuberculous sputum there is contained a virus which, it matters not whether it enter the organism in smaller or greater quantity, whether it be deposited in the lungs or in the peritoneal cavity, calls forth, without exception, nodules of tubercle-like structure in great number, while other organic non-tubercular substances either can not at all, or only under certain conditions, produce similar nodules, and even then in small number."

But when the *experiments* of Weichselbaum are examined we find a still more complete agreement with and support of Tappeiner. These experiments comprised eleven upon dogs. Concerning the results of the latter, Weichselbaum says: "In all these cases . . . there were found tubercles in the lungs and kidneys, in the former generally very numerous, in the latter only scattering." These experiments also comprised three with a watery emulsion of cheese. In two of these a stinking cheese (similar to Limburger) was used for inhalation. The two dogs died: the larger at the end of a month, after having received six inhalations; the latter at the end of five days, after two inhalations. The cause of death was gastro-enteritis, "while nothing of tubercle or anything similar was found." In the remaining one of these three cases, however, where a sort of cheese which did not smell badly was used for inhalation fifteen times in seventeen days, "twenty-four nodules the size of a millet-seed could be demonstrated in the lungs, and one submiliary nodule in each kidney, which showed a

structure similar to that of the tubercles in the first-mentioned experiments."

"For control, two dogs were used; in the one dog, one Pravaz syringeful; in the other one, two syringefuls of the same cheesy emulsion used in the last experiment were injected into the peritoneal cavity; in neither case, however, were nodules found. The same negative result followed injection into two other dogs of tuberculous sputum which had been boiled for an hour, while unboiled tubercular sputum caused an abundant eruption of tubercles in the great omentum and mesentery.

"Furthermore, water-diluted pus from caries of a rib was employed for twelve inhalations within seven weeks, whereby a few scarce nodules, of a structure similar, however, to that of the tubercles of the first experiments, developed in the lungs.

"Finally a dog was made to inhale, sixteen times in twenty days, a watery emulsion of the spleen of an ox without the occurrence of nodules in a single organ."

Thus it is seen that of all Weichselbaum's experiments reported in the paper above mentioned, *only two* (viz., one of emulsion of non-stinking cheese, the other of pus from a carious rib) gave any warrant whatever for that author's deduction that "also certain other organic substances (besides tubercle sputum) possess the faculty of exciting tubercle-like nodules."

In criticism of these *two* experiments, it may be justly objected that, in the present state of our knowledge, it is impossible to know that the two organic substances used did not contain tubercle virus. Indeed, in the case of caries, according to a very widely accepted opinion among pathologists concerning the nature of that affection, it is highly probable that the carious pus used did contain tubercle virus. As for the use of cheese in experiments to prove that other substances than those which contain tubercle matter or virus are capable of producing tuberculosis, the objection is also obvious. It is founded upon the fact that there is a widespread belief among medical men, based upon the actual observations and experiments of known and respected authorities, that it is not only possible, but even probable, that milk from tuberculous cows may contain tuberculous matter. Who, then, can know that the particular piece of cheese used for experiment in this case did not come from a tuberculous cow? What guarantee is there that in this emulsion some tubercular matter or virus was not suspended? We are well aware that there are those, and probably our author is one, who may think such an objection a little strained. But it must be remembered—for it seems to be often forgotten—that *the one point* to be determined by all those experiments to produce artificial tuberculosis is now not to learn if tuberculous matter can by inoculation produce tuberculosis, for this is now incontestable and is admitted by all respected investigators. The *one point* to be fixed and determined is whether or not substances which *certainly contain no tubercular matter or virus* can produce the same disease. For the settlement of such a question it is therefore necessary to be absolutely *assured* that the substances used for experiment can by no possibility contain or be accompanied by tubercular matter or virus.

We have now reached, in our reverse order, the first standpoint from which our author considers his first proposition: namely, that of *inoculation experiments*.

In the course of discussion the customary vein of the author becomes diversified now and then by the introduction of a spirit of captiousness, of which the following may be instanced as an example: Having again mooted the question of the identity of human tuberculosis with that produced experimentally in animals, our author proceeds to annihilate "at one fell swoop" both Dr. Koch and his knowledge of pathological histology by the declaration that "it is hardly within the province of the mycologist to teach us what is tubercle and what is not." (*Phila. Med. Times*, April 5, p. 488, right column, par. 6.)

There are one or two statements in this portion of our author's consideration of his first proposition which deserve to be noticed here.

Appropos of the discussion of Koch's inoculation experiments and statements concerning the relation of the tubercle bacillus to tubercular lesions, Dr. Formad seems to deny that there is any positive and reliable means of distinguishing the tubercle bacillus from other bacilli, for he objects to attempting to diagnose, by means of the bacillus, lesions which appear to be tuberculous and which contain tubercle bacilli, "because similar bacilli may be found in the lesions of various processes resulting in cheesy products (see bacillus chapter)." (*L. c.*, par. 4.) Here the author is not only in conflict with nearly the whole world of investigators, but, as usual, is also in combat with himself.

Referring, as directed, to the bacillus chapter, we find that the author, after a long review of the published observations upon the occurrence of the tubercle bacillus in the sputum and elsewhere, has summarized his views concerning the peculiar diagnostic characteristics of the tubercle bacillus as follows: "From our present knowledge of the occurrence of Koch's bacillus in the sputum, we must therefore conclude: 1. That the presence of bacilli is a valuable *diagnostic sign* of tubercular disease of the lung." (*L. c.*, March 22, 1884, p. 452, right column, pars. 2 and 3.)

Further: "To detect bacilli is a very simple matter, although by far not so easy as to prepare a specimen of urine and to find the all-important tube-casts." (*L. c.*, p. 445, right column, foot-note.)

And again we quote the author's words: "It (the bacillus tuberculosis) is concomitant with most tubercular lesions. It is *diagnostic of tubercular change*. It is, on account of its irritant properties, one of the causes of tuberculosis." (*L. c.*, Feb. 9, 1884, p. 338, left column, par. 3.)

Finally, we quote from his conclusions at the end of his paper: "From the above analysis of the bacillus question and of the *ætiology* of tuberculosis the conclusions follow: 1. That the bacillus of Koch is a valuable diagnostic sign of tubercular disease." (*L. c.*, April 5, 1884, p. 497, left column, par. 5.)

We might rest here, but at the latter end of the chapter referred to there are two important affirmations and arguments built thereon, which should not pass unchallenged. It is asserted that "bacilli, not distinguishable from tubercle

bacilli, are met with in lupus and leprosy." (*L. c.*, p. 453, right column, par. 6.)

When our author says, in support of his statement as to lepra, that "the bacillus of leprosy, in specimens which I had the opportunity to examine, appears to me also perfectly identical with the small forms of tubercle bacilli; although the lepra bacillus may, perhaps, look more sharp-pointed to the eyes of others, and may fail to take the brown stain" (*L. c.*, par. 7), he states his only argument in support of this declaration as to the lepra bacillus, and at the same time utters a sentence of which the last half is antagonistic to the first half. Each member of this sentence is assailable, and is, moreover, positively misleading. In estimating the value of our author's testimony concerning the perfect identity of the tubercle and lepra bacilli, it is important that something be known of the character and extent of the examination of the lepra bacillus he claims to have had the opportunity to make. It is not impertinent to this matter to inquire why the statement of the *whole truth* concerning this examination of the lepra bacilli has not been made. Is it possible that the author fails to appreciate the right of the reader to know the qualifying facts, that the few specimens of lepra bacillus examined by him were permanent preparations in the possession of others, that he could not personally vouch for their genuineness, and that he knew nothing of the methods by which they had been stained? Take the last member of this somewhat characteristic sentence; it also contains a characteristically inaccurate statement of fact. The concluding phrase thereof constitutes an expression of fact directly opposite to the truth, and reads as follows: "and (although the *lepra bacillus*) may fail to take the brown stain." The truth relative to the distinguishing micro-chemical reaction of the two bacilli in question is accurately stated thus: "and (although the *tubercle bacillus*) may fail to take the brown stain," while, on the contrary, the lepra bacillus may readily absorb it. (Refer to Koch's views on this point, quoted in the first part of this article.)

As to the author's objection that "bacilli, not distinguishable from tubercle bacilli, are met with in lupus," the answer is patent. First, let it be absolutely demonstrated that in none of the forms of lupus have we to do with a disease mainly local in the skin, but which in its nature is really tuberculous. Until that be done it is not only futile, but it is a waste of energy, to urge that the few scattering bacilli which very rarely have been found in the lesions of lupus are not genuine tubercle bacilli.

The author demands absolute proof at the hands of Koch and others who hold to the belief of the specific nature of tuberculosis. Let him also, as well as others, rely upon and advance evidence which is absolutely unassailable. There are now, and for many years have been, not only distinguished dermatologists, but also equally respectable pathologists and clinicians, who have been, and are, inclined to recognize lupus, scrofulosis, and tuberculosis as mere variations, due more or less to local conditions of the action of one and the same morbid cause.

There is one more argument used by our author in the discussion of his first proposition from the stand-

point of inoculation experiments which deserves to be considered.

In objecting to the use of the tubercle bacilli as one of the means of diagnosing a lesion in which they are imbedded, he says: "Besides, there are many spontaneous and artificially induced tubercular lesions in which bacilli could not be found." (*L. c.*, p. 488, right column, par. 4.)

Among the many considerations which weaken the force of this argument, the following may be mentioned. As customary, we state some of them by reproducing the author's own words.

In discussing the fact that tubercle bacilli are not always discovered even in phthisical sputum, in which, as every one knows, they are far more easily demonstrated than elsewhere, the author thus expresses himself: "The examination of sputum may thus in doubtful cases be quite misleading; for, if in any given case bacilli are not found, it should be taken into consideration . . . that the examiner may fail occasionally in any case to succeed in preparing a successful preparation of stained bacilli." (*L. c.*, March 22, p. 452, left column, par. 5.) How much the more is this true of the preparation and examination of sections of tissue in which the tubercle bacilli are imbedded, the experience of all workers shows. If occasional failure to see the bacilli in phthisical sputum does not invalidate the use of the tubercle bacillus as a *diagnostic sign* of the existence of the tuberculous process, certainly no man can consistently deny that the same tubercle bacilli may be used also as one of the means of diagnosis of tubercular products which contain them, simply because in such products the examiner may occasionally fail to see the tubercle bacillus.

As having a direct and important bearing upon the value of any deductions which the author may be disposed to draw from his failures to discover tubercle bacilli in certain tubercular lesions, it may be proper to examine his following statement: "A magnifying power of 400 diameters is nearly always sufficient to detect stained tubercle bacilli. In fact, we found that when we failed to find bacilli with a good $\frac{1}{2}$ objective, neither our $\frac{1}{2}$ Zeiss oil-immersion lens nor the Abbé condenser would reveal any when used (as we always do) for control." (*L. c.*, March 22, p. 446, left column, par. 1.)

Those who have been actual workers both with the high and the low power mentioned, both with and without the use of the Abbé condenser, can not but be struck with the absurdity of such a statement coming from one who would pretend to speak with authority about the presence or absence in the tissues of an object in every way so difficult of demonstration as is the tubercle bacillus when *in situ naturalis* in small numbers. It is, of course, possible, as every one knows, to use a magnifying power of 400 diameters, such as can be obtained by a good $\frac{1}{2}$ objective and a strong eye-piece, without the Abbé condenser, in the common clinical examination of sputa. But when any one says or ventures to intimate that he can, with even an approach to certainty, recognize isolated tubercle bacilli, in sections of tissues prepared for the microscope, without the aid of an Abbé or a similar sub-stage condenser and the use also of an excellent objective of very high power,

neither his negative observations nor the conclusions drawn from them will be credited by those who are practically familiar with both methods of examination. Yet our author has drawn most positive and important conclusions, not only from his failure to find any bacilli whatever in some tuberculous tissues, but also from his reported failure, in some instances, to find them in satisfactory numbers. From my own experience in the use of high and medium powers, with and without the aid of the Abbé sub-stage condenser, in the search for bacilli in the tissues; from the fact that I have never seen an Abbé condenser in use in the Pathological Laboratory of the University, or known such an instrument to be in common use there; as well as for other reasons not necessary to mention, I am free to confess that, for myself, I decline to accept these reported failures of the author as in any degree conclusive that in these very cases tubercle bacilli were not to be shown by proper methods and means of demonstration.

The author refers (*L. c.*, p. 446, right column, par. 4) to our joint examination, three months after our return to America, of a most beautiful and perfectly pure tubercle-bacillus culture with which Dr. Koch had kindly presented me. The flat salt-dish within which this culture was inclosed was opened for the first time in the University Laboratory, and some blood serum already prepared by the author was inoculated with a few of the scales. At the same time, several preparations of this culture were at once made for microscopic examination, the staining fluids belonging to the laboratory being employed. At the first examination of these preparations, made with the $\frac{1}{2}$ lens commonly used in that laboratory for the examination of sputum and other materials in searching for tubercle bacilli, it was impossible for either of us to determine whether we had under the microscope a pure culture or not. There were many rod-forms so short as to be practically unrecognizable as bacilli by means of that magnification and lens. Yet, when examined by the $\frac{1}{2}$ Zeiss homogeneous immersion, there was no longer any possible doubt that every bacterium visible was a characteristic tubercle bacillus.

Furthermore, the author refers, in his consideration of tuberculosis of the serous cavities, to four cases of "primary peritoneal and pleuritic tuberculosis" which have come under his observation during the last eighteen months, and takes occasion to state that "no bacilli could be discovered, even after repeated and careful search, in any of the lesions." (*L. c.*, Feb. 23d, p. 381, left column, par. 4.)

Inasmuch as the author has done me the honor of mention in the paragraph preceding the last quoted, I may, perhaps, be excused if I offer here some testimony of my own bearing more or less directly upon the last-mentioned negative observations of the author. Gross specimens of the abdominal lesions from one of several cases of primary tuberculosis of the peritonæum reported by our author as containing no tubercle bacilli recently came into my hands. A few isolated, small miliary nodules upon the peritonæum were snipped off carefully and quickly ground to a pulp (in a new agate mortar which had never been used and had been sterilized), with the addition of a few drops of water which contained no tubercle bacilli. Some of this pulp was spread

in a thin film upon a glass cover, in the manner of preparing sputum; this film was stained in the usual manner, after Ehrlich's method as employed by Koch. It was examined by me with a fine $\frac{1}{10}$ immersion objective, with the aid of an Abbé condenser, and was found to contain a small number of tubercle bacilli which were characteristically, although somewhat faintly, stained.

But there is yet a more serious reason for declining to accept as conclusive the assertions of our author concerning his own experience with the tubercle bacillus. Loyalty to the cause of pathological research, as well as the gravity of the subject discussed, demands that it should be stated. I refer to an evident disposition on the part of the author, frequently manifested even in print, to magnify and misrepresent the observations which he undertakes to report.

Perhaps one of the most glaring examples of such a disposition to be found in the second paper of the author is the following:

Speaking of the well-known experiments of Ziegler, in which plates of glass were inserted into the subcutaneous tissue, our author has thus printed his observations:

"Ziegler very properly declared the latter product to be tubercle tissue. I have had, and have at present, ample opportunity to corroborate the accuracy of these observations. Ziegler's experiments were repeated in the Pathological Laboratory of the University of Pennsylvania by Hammer, and at present are being carried on by Woodnut. By these experiments, made, with slight modification, after the method of Ziegler, under varying conditions and upon various animals, it was shown that the granulation tissue gradually gave origin to tubercle nodules. Furthermore, these experiments showed that *the tubercle nodules and cheesy changes ensue without the action of bacilli*, as the latter were found not to be present where proper care was taken during the execution of the experiment to exclude them." (*L. c.*, Feb. 9, 1884, p. 342, left column, par. 1.)

With respect to the above-cited experiments of Woodnut we have nothing to say except that he was during that time not yet even a graduate in medicine, but only a young medical student, presumably more or less skillful, or more or less careless and inexperienced. But what of importance there is to be said relates to the above-mentioned experiments of Hammer. It is simply this: that it is a matter of common knowledge among the university people that Hammer's experiments and observations on this subject were both begun and completed long before Koch's first announcement of the existence of the tubercle bacillus, and that no one was better aware of that fact than the author when that statement was deliberately written for publication.

We have now reached the end of our criticism of the manner in which our author has considered his first proposition in the one page and a half which he devotes to that matter. After having thoroughly and carefully examined the two papers published by our author on the ætiology of tuberculosis, we are convinced that there is ample justification for the declaration that it is difficult to find, from one end to the other of these two papers, any two consecutive pages of print which are not equally defaced with similar faults. But we stated at the outset that we possessed neither

the time nor the inclination to touch upon all that appeared to us objectionable.

We shall end this communication by a brief examination of the sort of logic by which our author concludes that the tissues of the scrofulous possess a specific anatomical structure, and that the ætiology of tuberculosis is thereby explained.

During the discussion, before the Philadelphia Medical Society, of the author's last paper on tuberculosis, we took occasion to state some objections to the acceptance of his hypothesis concerning the lymph-spaces of the so-called scrofulous. (See "New York Medical Journal," June 14, 1884.) The reasons then urged will not be repeated here, but we will limit ourselves at this time to pointing out some statements of our author which, to our mind, are fatal to his hypothesis. Before quoting these statements, however, it may be well to call attention to a very serious gap in the connection between this alleged peculiarity of the lymph-spaces of the connective tissue, which our author has as yet made no effort to fill up by direct observations. We allude to the fact that, while the author claims to have demonstrated, in the scrofulous, the existence of a peculiar narrowing of the lymph-spaces in the connective tissue of the skin, of the subcutaneous tissue, and possibly also of the intermuscular connective tissue, he has entirely neglected the lymph-spaces of the lungs, the liver, the spleen, the kidneys, and the bones. One does not need to be a pathologist to be cognizant of the extreme rarity of tuberculosis of the skin, and of the extreme frequency of tuberculosis of those very organs whose lymph-spaces have not yet been studied by our author.

We now proceed to indicate the difficulties which our author has, according to his custom, placed in his own way.

After having reaffirmed his former assertions and conclusions concerning the lymph-spaces in the connective tissue of the scrofulous, our author thus delivers himself: "For details of my researches in this direction, I must refer to my first paper upon this subject." (*L. c.*, Feb. 23d, p. 378, right column, par. 2.)

Referring to that first paper we find the following: "Comparing a large number of sections taken from corresponding parts of the bodies of rabbits and cats, it is also distinctly seen that the lymph-spaces are on the average decidedly narrower and fewer in the rabbit than in the cat. *The perivascular spaces are, however, equally free and similar in both.*" (*L. c.*, Nov. 18, 1882, p. 113, right column, par. 1.)

Returning again to the second paper, we find the subjoined statements as to how and where tubercle originates: "*Primary tubercle occurs as a mere infiltration of lymphoid cells in the adventitia of blood-vessels (a term synonymous with perivascular lymph-spaces), or as small nodular masses of lymphoid infiltration around blood-vessels or ducts of any kind; or tubercle tissue may organize within blood-vessels and various ducts.*" (*L. c.*, Feb. 9, 1884, p. 342, left column, par. 3.)

Of the occurrence of *secondary* tubercles thus he has written: "These seem to lie *in the perivascular lymph-spaces*, and are probably distributed throughout the body

mainly by means of these lymph-channels of the blood-vessel walls. Tubercles do not occur in avascular tissues." (*L. c.*, right column, par. 3.)

We confess our utter inability to see how the occurrence of tubercles in locations where the lymph-channels are admitted by our author to be "equally free and similar in both" the so-called scrofulous and the non-scrofulous animals can have anything whatever to do with peculiarities which may possibly exist in other places. Perhaps the inventive ingenuity and surpassing skill in engineering of our author may enable him to remove some of these self-imposed obstacles, or to vault over them or brush them aside. For ourselves, in their present shape they appear insurmountable.

After the author, by revising a statement here, retracting one there, and by filling up that gap and this, shall have succeeded in bringing his *hypothesis* into complete accord with facts and common clinical experience, it will then remain for him to show that the claimed peculiarity of the lymph-spaces of certain men does not have quite as much to do with the ætiology of the lesions of syphilis as with those of tuberculosis. (See Cornil on "Syphilis," American edition, by Simes and White, pp. 24, 25, Philadelphia, 1882, and "Clinical Lectures on the Physiological Pathology and Treatment of Syphilis," by Fessenden N. Otis, M. D., New York, 1881.)

In the foregoing incomplete criticism of the author's printed assertions concerning the ætiology of tuberculosis we have, as far as possible, purposely avoided a general discussion of the latter subject, and have intentionally adhered closely to the text of his own papers, and to that of a few of those to whom he refers.

Our sole object has been an endeavor to discover, if possible, what degree of reliance, as a witness whose testimony is in conflict with that of Koch and others, can safely be placed upon the observations and conclusions which our author has already published as his contribution to the knowledge of the ætiology of tuberculosis.

We readily confess ourselves greatly at a loss for an adequate standard by which to measure that degree of reliance which they intrinsically deserve, for, so far as our reading of the extensive, extremely varied, and conflicting literature of this much-discussed subject has gone, it appears that these contributions of our author stand unique and without comparison. Perhaps the only practical gauge, after all, is that which each one will apply for himself. We leave the application to be made.

Finally, we are also somewhat at a loss for proper terms with which to conclude. Since, however, in the preceding pages we have so frequently turned the words of the author against himself, it may not be improper to continue this course to the end.

"Thus, above all, *negative evidence* must be carefully inquired into, not by relying upon the crippled and sometimes misrepresenting and meager quotations of some compiling writers, but by submitting the original communications of the authors and experimenters to a careful perusal." (*L. c.*, April 5, 1884, p. 494, left column, par. 3.)

We have pointed out striking "instances of the way in which an experimenter with preconceived and peculiar ideas

upon a subject may unconsciously be misled in forming conclusions from his own experiments." (*L. c.*, April 5, 1884, p. 495, left column, par. 2.) We have at the same time indicated how our own author, as well as "some of the younger German pathologists and a few of the prominent English surgeons, under the influence of the bacillus craze, will make in publications assertions entirely unwarrantable." (*L. c.*, Feb. 9, 1884, right column, par. 1.)

"All of the above statements are made by a scientific man and pathologist, and offered as broad facts in full earnest. I only have to say that here evidently observation is substituted by imagination and mere speculation; and all this is done for the sake of the convenience in explaining a disease by pretty hypotheses." (*L. c.*, par. 2.)

ON FAT EMBOLISM.

By ROSWELL PARK, A. M., M. D.,

PROFESSOR OF SURGERY, MEDICAL DEPARTMENT, UNIVERSITY OF BUFFALO.

By fat embolism is meant a plugging of small arteries by minute drops of fluid fat which, having been set free somewhere in the periphery, are carried into the venous circulation and thence distributed to various parts of the system. Inasmuch as the capillaries of the lungs offer the first lodging-place, fatty embolism of the lungs is that which is oftenest met with, and consequently recognized and studied; but a similar condition of affairs may obtain in the brain, choroid, kidneys, or other parts, provided only that there have been sufficient *vis a tergo* to force the fat globules through the pulmonary capillaries and into the systemic circulation.

As will be presently shown, pathologists have been but recently made familiar with all that the title of this paper implies, and it is with a hope that I may do my share in contributing to a better appreciation of the subject that I have chosen it as the topic for this essay.

HISTORY.—Perhaps the first observation on record which deserves mention is one by Müller, who, in 1860, discovered that the choroidal vessels of a certain case were filled with fluid fat which was supposed to have come from an atheromatous aorta. Two years later Zenker* found the pulmonary vessels, after injury, filled with fat, while at about the same time E. Wagner† found in many cases the capillaries of the lungs filled with fluid fat, and was therefore disposed, from the direction in which it extended in these vessels, to explain a certain number of pyæmic cases by the fat embolism, an explanation now known to be fallacious. In other words, this fat was supposed to have come from some metamorphosis of pus, and to be in some way connected with the presence of metastatic abscesses.

In 1864 Flournoy met with the following case:‡ A man was brought to the Königsberg Surgical Clinic with a simple transverse fracture of the tibia, caused by the kick of a horse. On the following day he complained of great weak-

ness, became comatose, and died thirty-six hours after the injury. Von Recklinghausen made the section, and found small ecchymoses in the brain, heart, skin, bladder, conjunctiva, and retina; hæmorrhagic infiltrations of the tibial marrow for an inch each side of the fracture, a clot between the fragments, and great œdema of the lungs. Microscopic examination revealed fat in the arterioles, capillaries, and veins almost throughout the body, especially in the lungs, where the obstruction must have been almost complete.

Stimulated by the findings in this case, Wagner and Busch both entered upon a thorough study of the subject. In 1865 Wagner published* his study of forty-eight cases in which he had found the lesions under present consideration, of which fifteen were cases of speedy death after injury. By this, as by Busch's† demonstrations with cinnabar injections into the marrow of injured bones, the subject was materially cleared up. Busch also collected forty-three cases from various causes—twenty-four from fractures, three from acute peri- and osteomyelitis, seven from endometritis and metrophlebitis, four from acute suppurations in soft parts, and the balance from miscellaneous causes, such as ulcers on the leg, etc.

Finally, Bergmann experimented with intra-venous injections of oil, and clearly established that fatty embolism of the lungs and pyæmic processes were distinct from one another, though in accidental cases they might be simultaneous.‡ We also owe much to the earlier labors and researches of O. Webber, Uffelmann,* Schwick,|| Buttletswi,^ and Niederstadt.¶

Since 1869 it has been met with so frequently abroad as to occasion little or no surprise, and it is only at home now that, if one may judge by current literature, its frequent occurrence is not yet generally appreciated.

FREQUENCY.—It is difficult to form an accurate estimate with reference to the frequency of occurrence of fat embolism, but it must occur to a slight extent in nearly every case of fracture and laceration. Numerous observers have shown how uniformly fat embolism of the lungs, at least, happens after extensive compound and multiple fractures. Moreover, the symptoms so much resemble and so often complicate those of shock, that Czerny has suggested that many deaths heretofore attributed to shock were really due to this kind of embolism, and, without doubt, this is the case, both for the past and even for the present. Flournoy and von Recklinghausen, studying the subject at Strasbourg, showed that slight diffuse fatty embolism was to be found in ten per cent. of a miscellaneous series of two hundred and sixty dead bodies.

In 1879 Sinclair* had found accounts of one hundred and forty reported cases, with a mortality rate of thirteen per cent. Of this total number, eighty-four were of fracture, with sixteen deaths.

ETIOLOGY.—We may sum up the following, in their order of frequency, as the causes which, in the vast majority of cases, lead to fat embolism:

Injuries to bones, of all sorts, especially simple and compound fractures.

Lacerations of soft parts, especially of adipose tissues.

Surgical operations.

Acute periostitis and osteo-mylitis.

Rupture of fatty liver.

Certain pathological conditions, such as fatty degeneration of thrombi, icterus gravis, and diabetes.

MORBID APPEARANCES.—"One only needs to cut off with scissors a small piece of lung raised by forceps and to spread it out in water in order to see larger and smaller streaks of capillaries, and even larger vessels, filled with the highly refracting fatty mass."† In fact, fatty infarctions may be sometimes clearly made out by the naked eye, particularly in the lower lobes of the lungs.

Oil-drops have been found in the interior of clots in the pulmonary arteries and right heart, and even in veins leading from the site of injury.

Echymoses of the organs most affected are often found, and these often are met with in close conjunction with the fatty infarcti. It is as if the blood, not being able to work its way through the natural channels, had broken down the tissues and thus escaped.

When sections of these tissues, lungs for instance, are placed under a low objective, their capillary network, which under ordinary circumstances would be invisible, is seen to be more or less distended and injected with fatty material or fat drops, and quite plain to the eye. This same appearance would characterize any tissues thus affected. Such sections should be cut from parts well hardened in alcohol or similar medium. Osmic acid in one-per-cent. solution both hardens the tissues and stains fat black; if, then, small portions of lung and other parts be kept in this solution, or sections be immersed in it before mounting, the vessels will appear as if injected with some black mass. Such a demonstration is most interesting and convincing. This may be made even more so by placing the sections so stained in ether, when these peculiar appearances should at once disappear.

PATHOLOGY.—Numerous observers have noted that during operations and after compound fractures oil-drops are frequently seen floating on fluid or semi-solid blood, and this fact might lead to the supposition that the fat could gain access to the pulmonary circulation only by way of the veins; but it has of late been shown that it may be absorbed by serous surfaces, and that the embolic disturbances entailed after a certain amount of fluid fat has been passed into the heart through the thoracic duct are none the less

genuine, though usually less rapid and disastrous.* It is probable that in such cases as these a certain amount of fat is detained in the glands.

Scriba, after a number of painstaking experiments, has been able to establish † the fact that the severity of the symptoms depends on the quantity of fat in the circulation, the rapidity with which it enters, and the proximity to the heart of its source; and, indeed, that the symptoms may become so violent as to resemble those of entrance of air into veins.

The part played in the etiology of fat embolism by *vis a tergo* has been well shown by Déjérine, ‡ who found that fatty emboli were produced in greatest number when laminaria tents were introduced into the medullary canal. This shows the effect of pressure, be it of blood extravasation, muscular contracture, or inflammatory swelling.

It has also been pointed out that since the fat of bone-marrow, as well as of adipose tissue, is contained in membranous sacs, or so-called fat-cells, these membranes must be ruptured before their fluid or semi-solid contents can escape. This allows the fat to gather in fluid, movable masses, a fact alluded to by Fenger,§ and which explains the alarming character of the symptoms. Fat embolism is, however, rare in children, because their skeletons contain so little fat—an important point to which Minich has called attention.||

While this fat does not cause inflammation, infection, nor sepsis, *per se*, the possibility of entrance of micro-organisms into the system *along with* the particles of fat should still be borne in mind, though I am not aware that this has ever yet been noted.

The conditions which, *par excellence*, predispose to fat embolism are:

Openings in the walls of the blood-vessels.

Presence of fluid fat in the neighborhood of the same.

A certain *vis a tergo*, usually pressure of extravasated blood, which tends to force this fat through these openings.

Not desiring to digress too far from the purely surgical features of my subject, I will here only stop to mention that Saundby and Barling have reported^A nine cases of severe injury, none of which survived more than two days and in all of which fat emboli were found in the lungs. In the course of this paper they also state that they found these emboli in a case of diabetes with milky blood; but, since the fat globules were found in the clots present in the vessels, it may be that they were of post-mortem formation and due to the running together of oil globules.

In this connection it may be worth while to state that in diabetes the blood serum has occasionally a milky character, and it has been shown that under these circumstances the blood contains a profusion of fine, oily globules or mole-

cules. Whether, then, the fat embolism observed after death from diabetes is owing to this fat already existing, or whether to some fresh source, is not known. At all events, the two conditions are very similar, and differ merely in their prime causes. We know that in a diabetic patient, dying comatose, fatty infarcti have been found in the lungs and kidneys, as also that a diabetic may die comatose, the blood showing quantities of molecular oil without a single appearance of fatty embolism proper.

Moreover, in a case of farcy reported by Bendall (Saundby and Barling, *l. c.*) the presence of fat emboli was clearly demonstrated, while a similar case, investigated by Boyd, gave negative results.*

From all of which we may then infer that fatty emboli may cause trouble under very diverse conditions, that we need never be surprised at finding them, and that the more carefully we search for them the oftener we shall find them.

It is a matter not only of interest, but of pathological importance, to trace, if possible, the destination of the fat which may thus have entered the circulation. With that which lodges in the pulmonary capillaries we have already made some acquaintance. That which is forced through them passes into the general circulation and may cause disturbance in the brain or cord, and thus affect the vital functions or cause motor and sensory symptoms. Or, more frequently, it is arrested in the liver, or in the glomeruli, whence it is excreted with the urine. In the latter case thin sections of the kidneys, properly stained, would show the vasa efferentia, glomeruli, and tubules filled with fat.

Particles thus arrested, instead of being excreted, may be forced into the veins again and thus establish a milder and secondary embolism of the lungs. When fatty emboli occur in the liver, it is probable that the hepatic cells take up a certain amount of it. In other cases, when the primary condition is not rapidly fatal, inflammatory processes may be set up in the lungs and brain as a result of ecchymoses and of the presence of emboli, as a case reported by Riedel† abundantly shows. One would naturally conclude, from a careful study of this case, that in the old and intemperate a graver prognosis should be given in cases of fatty embolism; their hearts are weakened and their power of resistance notably diminished. Indeed, there is reason to think that many cases of hypostatic pneumonia take their origin in this way.

Undoubtedly, then, fatty emboli may produce disastrous secondary effects.

SYMPTOMS.—General condition: Debility and malaise, rapidly increasing. Countenance pale, becoming anxious and then distressed, and at last the face is cyanosed, with pupils contracted. Reflex excitability is gradually lost. Patients are usually at first excited, then wildly or quietly delirious, then somnolent, and finally comatose. In rare cases, depending on the amount of cerebral disturbance, vomiting, spasms, or paralysis may precede death.

Respiratory Organs.—The respiration rate gradually increases from the normal up to fifty or even sixty to the

minute, breathing becoming stertorous. Dyspnoea, increasing in intensity until it becomes agonizing, sometimes marks these cases. Cheyne-Stokes respiration may also be observed in the earlier stages. At the last there may be foam, sometimes bloody, from the mouth, as in oedema pulmonum; or during the course of the symptoms there may be hæmoptysis. With the stethoscope large bronchial râles are heard, which change until they become tracheal.

Circulatory System.—The pulse is weak, frequent, and irregular, fluttering toward the close. The temperature range is by no means constant; usually it is at first below the normal, and may in some cases remain so; in other cases it fluctuates from hour to hour, and may vary from the normal by wide limits either above or below. In other words, its range is atypical.

The foregoing constitutes a brief summary of the more important symptoms, few of which are constant and none pathognomonic. If, however, along with these, fat or oil globules can be detected floating on the urine, the diagnosis may be easily made; and when the above symptoms are clear and a majority of them evident, and are accompanied by a history of accident or operation, we shall seldom err in diagnosing fat embolism.

As a rule, they set in within thirty-six to seventy-two hours after the lesion causing them. I had supposed that the case which I shall report at the close of this essay had developed the symptoms and run its fatal course in less than the shortest time on record, until later experience and a closer study of the literature of the subject convinced me to the contrary. A French surgeon (Déjérine) has reported a case fatal within seven hours; and, if my diagnosis of another case is right, which unfortunately I could not verify by autopsy, I was an interested spectator of a case that proved fatal in a little shorter time even than this.

DIAGNOSIS.—In general, the diagnosis is to be made by eliciting a history of violence or of operation, by the sudden and painless onset of the symptoms above given within the average length of time, by a lack of other and sufficient cause therefor save those furnished by a history of some lesion, by the negative result of ordinary physical examination, and by the absence of paralysis and of all the usual evidences of central lesions of the nervous system and of valvular disease of the heart. Uremia, albuminuria, and diabetes can be excluded by examination of the urine, while if oily globules are found upon it they will speak conclusively for fat embolism.

Inasmuch as it is usually in surgical cases that we have to encounter this condition, it is from other surgical affections that we shall most often have to differentiate it. The symptoms usually come on too rapidly for those of septic trouble, although I can imagine that a mild and non-fatal form of fat embolism might be mistaken for septicæmia. As distinguished from shock, there is this point to be noted: that, by the time the symptoms of embolic disturbance are at their height, all, or nearly all, shock should have subsided. Thrombosis, as from phlebitis, and embolism from other causes, may produce rapidly fatal results, and here is the diagnostic sign in that they are usually fatal in less time than fatty emboli require to lead to the same result.

* "London Med. Record," November 15, 1862.

† Riedel, "Deutsche Zeitschrift. f. Chirurgie," 1877, viii, p. 572.

With a proper appreciation of the possibilities and probabilities of its occurrence, fat embolism is not likely to be overlooked very often, and when it is it will be in those fortunate cases where recovery follows and the question of diagnosis is, if possible, one of minor interest.

PROGNOSIS.—This must be in proportion to the extent of the injury, the proximity of the lesion to the heart and lungs, and the general condition, age, and physical characteristics of the patient. In extensive lacerations and fractures there are greater possibilities for entrance of fat into the circulation, as well as for constant increase of the amount.

Realizing that a slight amount of fat embolism occurs in almost every fracture in adults, we shall be prepared to understand the symptoms of restlessness, slight agitation, respiratory and circulatory disturbance, which can often be noted by a careful observer after a simple fracture, and understand their exact import while still waiting confidently for a speedy cessation of the same.

But, when the symptoms become severe, a most guarded and, generally speaking, unfavorable prognosis must be given. If the heart can be given sufficient vigor and endurance to continue pumping the blood with its burden of fat through the pulmonary capillary circulation, then the most imminent danger may be escaped. This it may do until either the capillaries of the brain become stopped up and its source of motive power thus paralyzed, or until the general capillary circulation is similarly obstructed, when it must finally stop, incompetent for the task.

DURATION OF SYMPTOMS.—The duration of the grave symptoms may vary considerably. When the capillaries of the brain become quickly plugged, death will take place more rapidly than when the lungs are chiefly affected. In the former case a few hours—two to six—may end the patient's life. If the circulation through the lungs be most at fault, the patient may die in from six to forty hours. When well-marked evidences of fat embolism are present, but are followed by recovery, the worst of the trouble will probably be over within forty-eight hours after it began.

TREATMENT.—Obviously the proper treatment will be to augment by every judicious means the power of the heart to force the load of fat through the venous and into the arterial system. If this can be done, the fatty matters will probably be emulsified or saponified by the alkalies in the blood.

The more the fractured or injured part is disturbed, the more fat will presumably enter the circulation. Consequently the injured part should be kept absolutely at rest. When a case of injury is complicated by delirium tremens, this is much more difficult, and may even justify the use of opiates when they would otherwise be contra-indicated. At all events, immobilization is always indicated as a precautionary measure.

As concerns internal treatment, the most powerful cardiac stimulants are called for—e. g., alcohol, digitalis, strychnine, ether by the mouth or under the skin. In fact, in this as in other respects, treatment must be symptomatic. On purely theoretical grounds, I should be strongly inclined to suggest the administration of oxygen, by inhalations of the gas, as strong as could be well borne.

DANGERS OF FAT EMBOLISM AFTER OPERATIONS.—I have excellent personal reasons for thinking that this is an important point to be considered in summing up the dangers of certain operations. Vogt has particularly called attention to the danger of fat emboli after resections. Alluding to the studies of others, and the report of a fatal case by Lücke,* he rehearses in detail a case of his own.† In this case—a knee—the bone substance was found to be in a condition of extreme fatty degeneration. He therefore deduces the lesson that when, in resecting bones and joints, we find the bone in this condition, and when, as in case of the knee joint, we want to bring bone-ends in close apposition, there is the greatest necessity for establishing unusually free drainage, and that, if circumstances make this impossible, we must proceed at once to amputate.

Besides the cases which I shall report below, I would refer the student of the literature of fat embolism to cases reported, among others, by Czerny,‡ Riedel,§ Scriba,|| Pinner,^ Zwicke,◇ Boettscher,‡ Socin and Burckhardt,‡ Fenger,‡ Fitz,** and Southam ††; also to the following works of reference: "Deutsche Chirurgie," Lfg. 3, p. 265; Holmes's "System of Surgery," 3d ed., London, 1883, vol. i, p. 427; "International Encyclopædia of Surgery," vol. i, p. 371; Stimson's "Treatise on Fractures," p. 133; "Index-Catalogue of the Library of the Surgeon-General's Office," vol. iv, article *Embolism* (Fatty).

Cases I and II I report with some hesitation, since the diagnosis was not verified post mortem, and yet there is not the slightest doubt in my own mind that they properly belong here.

CASE I.—A young woman was operated on for caries of the ankle. The course of the disease prior to the operation had been very chronic. The operation itself did not differ in any way from the average, and recovery from the anæsthetic was prompt and satisfactory. On the morning of the third day she was found unconscious in bed, and she died comatose in a few hours. I am reporting this case from memory, as it occurred at a hospital of which I was then an interne. This was before the matter of fat embolism had ever been broached in an American journal, so far as I know, and it is not strange that an autopsy, made by one of our own number, failed to clear up the mystery of her death, for we found nothing which at the time appeared to us wrong; still, her case is yet fresh in my mind, and, as I recall her symptoms clearly, I am as sure as I well can be that, without question, it should be placed in this category.

CASE II.—During the past winter I was present at an operation for removal of a cancerous breast from an extremely fleshy woman. The operation was made by one well qualified to undertake it, and passed off without anything unusual transpiring, except, perhaps, that it was somewhat prolonged. The

†† "Lancet," July 10, 1880.

gland was imbedded in adipose tissue, and I noted both that venous oozing was free and that the fatty tissue crumbled readily under the sponge, and even seemed to melt down. The operation was begun about half past ten. The lady never became completely conscious, and died comatose about five o'clock, with nearly every symptom that I have detailed above. I am well aware that in this case the trouble may be ascribed to the anæsthetic, and with some reason; and yet, all things considered, I hold that the case can be properly classed as fatal from fat embolism. Unfortunately, autopsy, which might have cleared this all up, was denied.

CASE III.—Vito Pasuento, aged forty-one, laborer. While working for the Wabash Railroad, October 18, 1882, he was thrown from a car to the ground and, in some way never made quite clear, was badly injured. The injury took place at 8:30 A. M. Owing to its occurrence out on the road, he was not seen by any medical man until 1 P. M. At this time he was seen by some country physician, who did nothing for him (nor had anything been done in the mean time), except that he was laid on a rudely devised bed in order to be sent to Chicago on the first train. Arrived in that city, as the company's surgeon, I had him taken at once to the hospital, where he was admitted about 9 P. M. During these thirteen hours he had received a little nourishment, but no further attention save that one of his fellow-laborers had rudely tied a handkerchief around the worst injured limb. At no time had he had any gentle handling, but rather such as a carcass might receive.

At 9 P. M. I anæsthetized him with the alcohol, chloroform, and ether mixture I was in the habit of using at the hospital. I found a simple fracture of the right tibia an inch and a half below the knee, also a compound fracture of the left femur at about its middle, with a most extensive laceration extending from this height down to the inner side of the knee, extending down to but not into the joint. These injuries I treated in the conventional way, immobilizing the limb and establishing free drainage. The patient rallied from the anæsthetic only partially, fell into a deep sleep which by midnight became coma, and died at 4 A. M., twenty hours after the injury.

Section, Twelve Hours after Death.—The only points of special interest here are that, aside from fatty degeneration of the heart and fatty infiltration of the liver, both to very moderate extent, the picture of fatty embolism, as given above under the head of "morbid appearances," was complete. Fluid fat floated out on the blood after opening the heart, and sections of the lungs, placed under the microscope, showed profuse fatty injection of the capillaries.

CONCLUSIONS.—In the light, then, of these and numerous similar cases, and of careful experiments and pathological investigations, we are justified in formulating the following conclusions:

1. Fat embolism in varying degrees of severity is not an uncommon complication of surgical accidents and operations.
2. It may be so mild as to be lost sight of in the general condition of shock, or, perhaps, more properly speaking, it is one factor of a condition of prolonged shock.
3. Our knowledge of the subject will be greatly increased when we appreciate the possibilities of its occurrence and observe our cases more closely, watching for the appearance of fat in the urine, of slight dyspnœa, etc.
4. When prostration and loss of blood have been great, a moderate amount of embolic disturbance of this kind may serve to turn the scales against a patient who would have otherwise recovered.

5. By a proper understanding of this subject certain deaths may be explained which otherwise seem inexplicable.

6. Treatment can only be symptomatic, but may accomplish something.

7. Autopsies should be so conducted as to reveal this condition when present.

305 DELAWARE AVENUE, BUFFALO, N. Y.

A PAROVARIAN CYST WITH A TWISTED PEDICLE, ATTENDED WITH PERSISTENT UTERINE HÆMORRHIAGE.

By ELIZABETH M. CUSHIER, M.D.,

ATTENDING PHYSICIAN TO THE NEW YORK INFIRMARY FOR WOMEN AND CHILDREN.

For the history of the following case, prior to the patient's entering my service at the New York Infirmary, I am indebted to Dr. Annie S. Daniel, physician to the outpatient department, under whose care the patient had been:

A girl, sixteen years of age, of German parentage, had an attack of chorea four years ago, and the affection lasted two years. Since that time she has been very nervous, and has had occasional convulsions, not attended with loss of consciousness. She first menstruated at the age of fourteen. During the first year the flow was regular and painless. Last summer there was suppression of the menses for nine weeks, and this was followed by a profuse flow. Since that time her menstruation has been too frequent and profuse. Four weeks since there was severe hæmorrhage, and from that time there has been no complete cessation. One week ago the physician in attendance found it necessary to tampon the vagina, owing to the excessive loss of blood at that time.

Dr. Daniel saw the patient for the first time March 20th. The girl then presented the following condition: She was excessively pale, and complained of extreme weakness; apart from this, there were no symptoms, save that of uterine hæmorrhage. On examination, the vagina was found filled with clots. The external os was open, and there was a tumor in the median line, reaching half-way to the umbilicus. There was no sensitiveness of the abdomen, nor of the pelvic organs, and there was no odor to the discharge. The lungs were normal. There was a systolic murmur at the apex of the heart, with a loud hum in the jugular veins. The urine was normal. The bowels were very much constipated. She was taking but little food.

The treatment at this time consisted in efforts to arrest the hæmorrhage, for which purpose ergot and gallic acid were given and the hot vaginal douche was employed. An enema was also given, to move the bowels. For some hours after a copious stool there was a diminution of the uterine flow, but again, on the 24th, there was a profuse hæmorrhage, with the escape of enormous clots. On the 25th the girl fainted as she was moved from the bed, and, on recovering, she had convulsive movements of the arms and legs; her eyes were wide open, her neck was rigid and retracted, and her breathing was stertorous. This condition lasted for about an hour and a half, when it passed off, the treatment having consisted in the application of a sinapism to the nape of the neck and the administration of spiritus ætheris compositus.

On the 26th the patient was sent into the infirmary, and on the following day I saw her for the first time. There had been quite a profuse flow during the preceding night, and for the first time the temperature was elevated, being 100.3° F. The pulse was 110. The girl was completely blanched, and the pulse was

rather feeble. On vaginal examination, the external os was found open, admitting the finger readily, and the uterus was apparently as large as in pregnancy at about four months and a half. The rather peculiar softness of the tumor that was felt led to a very careful examination. The mass occupied a position exactly in the median line, and pressure on it gave an impulse to the finger upon the cervix, while movement of it in any direction caused a corresponding movement of the uterus, as ascertained also by vaginal touch.

As the girl, on being questioned, admitted the possibility of pregnancy having existed, it was presumed that some abnormal result of this condition was present; and, as the hæmorrhage had been so profuse, and had continued so long a time, the question was not so much of an existing pregnancy as of some product of a conception which had taken place during the previous summer, from which time the hæmorrhage dated. The introduction of a sound threw no light upon the matter; it entered only three inches. Still, the tumor felt could not in any way be separated from the uterus. The examination was made very carefully, as has been stated, because of the peculiar softness of the organ, which had raised a doubt as to the character of the trouble with which we had to deal. It was inferred, as a result of said examination, that we had to do either with a uterus which still contained a product of conception, of a few months' standing, which, having become organized, formed an obstacle to the admission of the sound; or with a fibroid of the fundus which had undergone cystic degeneration and, as is not infrequently the case, was accompanied by fungosities, which would explain the hæmorrhage. The indications for treatment were, in our judgment, to dilate the uterus, ascertain the cause of the exhausting hæmorrhage, and, if possible, remove it.

On the 29th three very small laminaria tents were introduced. It was impossible to pass more through the internal os. The tents were introduced with all the necessary antiseptic precautions. They had been placed in a solution of carbolic acid (1 part to 8 of glycerin), and, after being rinsed from this, in a 1-to-20 solution, from which they were carried into the uterine cavity. The vaginal tampon was carbolized with a 2.5-per-cent. solution. The next morning, after the removal of the first tents, four larger ones were readily introduced, the same precautions being resorted to. On the afternoon of the same day the patient was etherized, and the tampon and tents were removed. As the latter were withdrawn from the uterus, the internal os contracted so rapidly as to resist the removal of the last one. Exploration with the finger was, of course, impossible, but a blunt curette was introduced, in order to ascertain if fungosities were present. It entered to the depth of three inches, and, meeting with no obstacle, was drawn over the surface of the endometrium and withdrawn, without any result. A small silver probe was then introduced, in order to ascertain whether it would not enter farther into the uterus, possibly past some projection into the cavity preventing a correct estimate of its length—but with no more satisfactory result. The diagnosis remained, therefore, incomplete, and the cause of the hæmorrhage still a mystery. No further efforts were made to expand the uterus, as the condition of the patient did not justify it. She did not rally very well from the anesthesia; she vomited incessantly, and could not retain either food or stimulants. Attempts to give nourishment by the rectum were not more successful, and soon a diarrhoea set in which occasioned several stools during the night.

The next morning the patient was extremely weak; her hands were cold and covered with sweat; her pulse was 130, feeble and irregular, and her temperature was 97°. Nutritive enemata were again tried, and brandy and morphine were given hypodermatically. The enemata were retained until 2 P.M.,

when food was again given by the mouth. For two hours it was retained; then vomiting again set in, and the bowels began to move still more frequently. From this time there was an occasional rallying from this desperate condition, when the pulse would become a little stronger, but there was a progressive decline until April 1st, when the patient died. On the previous evening the temperature rose to 104° and the pulse to 180. She was at no time unconscious, nor was there pain at any time; on this day the vomiting and purging were almost constant. Until about fifteen minutes before death the respiration was but slightly altered; from that time it was very labored.

Post-mortem Examination, nine hours after death.—On opening the abdomen, a sac was discovered, lying just above the pubes, and presenting somewhat the appearance of a distended bladder. On carrying the hand down into the pelvis, the uterus could not be detected at first, but was eventually found to be so completely capped and covered in by the cyst which lay upon it as to seem a part of the latter. Further investigation proved the tumor to have its origin in the right broad ligament, and its pedicle to be formed by the broad ligament with its vessels. The Fallopian tube was twisted twice upon itself quite close to the uterus, and thus the cyst was turned over upon this organ in such a manner that the tube crowned its upper surface, extending from right to left, while the uterus fitted into a depression in its elastic walls.

The ovary of the same side had undergone cystic degeneration, and was of about the size of a walnut. The left ovary was normal. The peritonæum was healthy. The abdominal organs were extremely pale, but otherwise healthy.

At the apex of the right lung there were numerous old adhesions. The entire lungs were very oedematous. The heart was normal in size, but its tissue was very pale, and the mitral valve was thickened and insufficient. There were fibrinous clots in both ventricles, the one in the right cavity extending far into the pulmonary artery. On section of the uterus, the lining membrane was found thickened and intensely congested, but otherwise healthy.

The points of interest in this case are:

1. The question as to the cause of the hæmorrhage.
2. The difficulties in diagnosis.
3. The cause of the speedy death after the introduction of the tents.

In regard to the first, as has been stated, the lining membrane of the uterus, although thickened and intensely congested, bore no trace of a placental surface; indeed, the history of suppression of menstruation for three months, followed by a profuse flow, dated from the previous July, and, had pregnancy then existed, sufficient time had elapsed for all traces of it to disappear. Fungosities, so frequently found as a cause of similar losses of blood, were also looked for in vain. There was, therefore, nothing in the uterus to account for the hæmorrhage.

The examination of the heart revealed a moderate degree of insufficiency of the mitral valves, but evidences in other organs of disturbance of the circulation from this cause were entirely wanting, and it would certainly not account for the uterine hæmorrhage.

It seemed at first, therefore, as if even the post-mortem would give no aid in determining the diagnosis. On further consideration, however, the thought was suggested that in the twisting of the pedicle of the tumor might be found the explanation of the main symptom. A careful examina-

tion of the uterus and tumor, which had been removed together, showed that the entire broad ligament was so stretched as to admit of this twisting upon itself, and that in its turns were included the Fallopian tube and numerous blood-vessels. The former, below the twisting, was enlarged, when inflated, to the size of the index-finger, and the latter also were very much dilated. As these vessels belong to the pampiniform plexus, and as the return blood from the upper part of the uterus is received by them, the twisting above mentioned must have seriously interfered with this return current, and so, by inducing a very extensive degree of congestion of the organ, have favored the persistent hæmorrhage from its mucous surface. It seems, at least, very reasonable, in the absence of any other explanation, to account for it in this way.

The writer is aware that similar twisting of the pedicle in ovarian tumors, even to the extent of so interfering with the nutrition of the growth as to cause gangrene, is not accompanied by the symptom present in the case related, and this may give rise to a doubt as to the twisting of the pedicle having been the cause of the hæmorrhage. It must be taken into consideration, however, that the ovary, although situated in such close relation to the broad ligament, must, as it becomes pediculated, only take to itself that portion which distinctly belongs to it, and which would include only the ovarian vessels, leaving those of the uterus free in front of and below it. In a tumor of the broad ligament things may be quite different, as in the case recorded, where it was developed in such a way as to involve a great part of the ligament, as shown by the Fallopian tube occupying a central position above the tumor, which spread out on both sides of it. In such a case the pedicle would be composed of a greater part of the broad ligament itself, and would necessarily involve all the vessels contained in it. This twisting, which might not interfere with the arterial supply of the organ, might, nevertheless, owing to the diminished resistance of the veins of this great plexus, very seriously impede the return current from the uterus, and so result in hæmorrhage.

It may seem strange that the tumor was not readily distinguished from an enlarged uterus, for which it was mistaken. This error, however, will admit of explanation. The growth occupied a precisely central position, and was so closely adapted to the uterus that it was impossible to separate the two during life; indeed, any movement of the one imparted a similar movement to the other. Even when the patient was under the influence of ether, the most careful manipulation failed to distinguish the growth from the organ which lay beneath it. The fact that the measurement of the cavity of the uterus did not agree with the dimensions of the mass as ascertained by conjoined manipulation, as well as the fact that there was a peculiar softness about the tumor, only pointed to the probability of its having been developed in the upper part of the uterus and undergone cystic degeneration. It is believed, indeed, that nothing short of abdominal section would have thrown light on the true nature of the case with which we had to deal.

In regard to the cause of death: while at first sight the history of the case after the introduction of the tents may

point to them as the main factor, and while the danger of septicæmia from the use of these indispensable instruments in gynæcological practice must be admitted, still, a careful study of the case in question has led to a different conclusion. In the first place, all antiseptic precautions were taken, and, in the very large experience of the writer in the exploration of the uterus by means of tents, no harm has ever resulted where such precautions had been regarded. Moreover, the post-mortem gave no evidence of trouble in the pelvic vessels or lymphatics, nor was there any irritation of any portion of the peritonæum.

It becomes necessary, therefore, to seek for the explanation elsewhere. The girl was anæmic to the last degree, as a result of the repeated hæmorrhages—hæmorrhages at times so profuse as to require tamponing of the vagina. On the day previous to any operative procedure the temperature showed a slight elevation, and the pulse was quickened, pointing to beginning trouble of some kind, possibly the initial stage of irritation on the part of the gastro-intestinal tract, which afterward became very severe. From the time of the first introduction of tents the stomach absolutely refused to retain even the slightest nourishment, and within twenty-four hours an uncontrollable diarrhœa had set in. This circumstance, added to the condition of profound denutrition already existing, could not fail to be most serious in its results. No doubt there was a predisposition to this disturbance on the part of the gastro-intestinal tract, as an effect of defective assimilative function due to the anæmia, and, when it finally became pronounced, it so greatly aggravated the already desperate state of things as to remove all chance of recuperation.

Book Notices.

A Treatise on Ophthalmology, for the General Practitioner. Illustrated. By ADOLF ALT, M. D. Chicago, St. Louis, and Atlanta. J. H. Chambers & Co., 1884. Pp. xvi-244.

DR. ALT adds another to the constantly growing list of treatises on ophthalmology for the general practitioner, and, on the principle that the supply is regulated by the demand, there would seem to be a place for it in medical literature. The work consists of about two hundred and fifty pages, printed in fine large type on good paper, but the illustrations, which are quite numerous, are most of them poor, and many of them very poor—quite unworthy of the text. The contents are divided into twenty-six chapters, in which the author has aimed to give the general practitioner a clear idea of the principles of ophthalmology, and to guide him in deciding how far he may with safety treat any given case of disease of the eye, and when it will be necessary to call in the aid of a specialist. The descriptions of disease are generally clear and concise, and in the matter of therapeutics thoroughly sound and abreast with the most recent prevailing ideas of modern ophthalmology. This was to be expected from the author's general reputation. It is much to be regretted that the value of the work is so much detracted from by the cheap and unfinished character of the illustrations. This is especially noticeable in the chapters on diseases of the eyelids and conjunctiva, and in some of the illustrations of fundus disease. We are glad to see how decidedly and clearly the

author distinguishes between membranous and diphtheritic conjunctivitis as two distinct diseases, though the treatment for both may be the same. On all points of pathology Dr. Alt is especially strong. The chapter on diseases of the eye due to other diseases of the general system is a judicious exponent of certain modern views held by ophthalmologists, which it is very important that the general practitioner should understand. We can but add that the practitioner will get nothing but sound advice from a perusal of the book.

Clinical Demonstrations on Ophthalmic Subjects. By J. R. WOLFE, M. D., F. R. C. S. E., Senior Ophthalmic Surgeon to the Glasgow Ophthalmic Institution, etc. With Illustrations. London: J. & A. Churchill, 1884. Pp. 54.

This little brochure is divided into four parts, which treat, respectively, of transplantation of conjunctiva from the rabbit to the human subject; transplantation of skin-flaps from distant parts without a pedicle; an operation for the cure of detachment of the retina; and tubercle of the iris and ciliary body. All the articles have been published before at different times and in different journals. The first and second are the most important, and are both illustrated with woodcuts and photographs. In the second article, on the transplantation of skin-flaps without a pedicle, the author emphasizes the importance of freeing a skin-flap of all areolar tissue and of properly fixing it in its new place, if we wish it to adhere to a new surface by first intention or agglutination. He avoids all irritant substances in the dressings, such as carbolic acid, and deprecates the use of goldbeaters' skin. He uses no sutures, but molds the flap into position. In the third article, on detachment of the retina, Wolfe advocates the paracentesis of the sclera at a point corresponding to the site of the detachment. The lips of the conjunctival wound are separated with strabismus-hooks, and, to guard against rotation of the eyeball, he has devised a sort of steel thumb, which is put upon the index-finger of the left hand of the operator, and the point, which is provided with a stop, is pushed through the conjunctiva and sclera and keeps the eye steady. The sclerotome is withdrawn slowly, and gentle pressure is made upon the eyeball in the track of the receding lance by means of a fine spatula. The lips of the external wound are then brought together with a fine silk suture, and both eyes are strapped with court-plaster. The patient is kept in bed in a dark room for three days, and the dressing removed on the sixth day. The author has had excellent results in a number of cases. The little book is an interesting contribution to practical ophthalmic surgery.

The Refraction of the Eye. A Manual for Students. By GUSTAVUS HARRIDGE, F. R. C. S., Assistant Surgeon to the Westminster Ophthalmic Hospital. With Eighty-seven Illustrations. London: J. & A. Churchill, 1884. Pp. xi-204.

THE author has here presented to the medical profession an admirable little work on a somewhat abstruse subject, of practical value, though we question the wisdom of relegating the examination of cases of errors of refraction, and the prescribing of glasses, to the general practitioner. "No book, nor even the knowledge gained by watching others who are thus employed, can take the place of the dexterity acquired by practically working out a large number of cases of refraction." These are the author's own words, and, from the nature of things, such practical dexterity can only be acquired by the specialist. The opening chapter, on optics, is brief but well written, and very necessary to a proper understanding of the subject, for its details underlie the whole subject of refraction. It is gratifying to find in this work a thorough adoption of the metrical system

of numeration, which has met with so many obstacles to its introduction into general use. There is a chapter on retinoscopy, which term the author proposes to change to umbrascopy, as a better term. The illustrations are numerous, and most of them good, though it is difficult to convey a proper idea of the fundus of the eye by a woodcut, no matter how carefully made. The work also contains a set of Jaeger's test-types, a set of Pray's test-types for astigmatism, and a set of test-letters for distant vision. The type and paper are excellent.

A New Method of treating Chronic Glaucoma, based on Recent Researches into its Pathology. By GEORGE LINDSAY JOHNSON, M. A., M. B., B. C. Cantab., etc. With Illustrations. London: H. K. Lewis, 1884. Pp. 48.

THIS little book of fifty pages is an elaboration of a graduation thesis, in which the author seeks to establish the proposition that "the ordinary method of treatment for glaucoma by iridectomy, though highly successful in acute forms of the disease, is, nevertheless, both uncertain and unsatisfactory in chronic glaucoma." He reviews the recent advances made in the pathological anatomy and physiology of glaucoma, and concludes the second part of the work with a series of eight propositions, to the majority of which most working ophthalmologists will agree. He maintains that the reason why iridectomy fails in chronic glaucoma is because the primary obstruction depends on slow and gradual changes in the ciliary body and the tissues round the angle of the chamber, by which the connective tissue becomes increased, and, contracting, tends to narrow and imprison the lymph-spaces and to firmly tie down the iris against the contiguous cornea, so that to remove the iris up to its root becomes an impossibility. Johnson recommends a long paracentesis of the sclera with a double-edged modified Wenzel's knife. The point of the knife is entered about 4 mm. behind the sclero-corneal junction, and should penetrate nearly half an inch, the flat side of the instrument lying somewhat obliquely to the long axis of the eye. The knife is to be withdrawn with care. The eye is then bandaged until the wound has healed. The statistics of this operation, in the hands of Johnson and some others, justify all that is claimed for it. The little book has several illustrations, and is an interesting contribution to ophthalmic literature.

The General Practitioner's Guide to Diseases and Injuries of the Eye and Eyelids. By LOUIS H. TOSWILL, B. A., M. B. Cantab., M. R. C. S., Surgeon to the West of England Eye Infirmary, at Exeter. London: J. & A. Churchill, 1884. Pp. viii-147.

THIS little volume treats only of those diseases and injuries of the eye which are commonly met with by the busy general practitioner, and is in its main points to be commended, though objection might with propriety be taken to the advice given by the author, in speaking of purulent ophthalmia, to apply from four to six leeches to the temple or brow; they do very little good, and may do harm. Another objection might be made against the continued use of the barbarous term *corneitis* in place of *keratitis*. The treatment recommended for the various inflammatory diseases of the eye and eyelids is sound, and the author is wise in advising that all cases of operation upon the eye be referred, so far as possible, to the ophthalmic surgeon.

NEW YORK, SATURDAY, AUGUST 16, 1884.

RAILWAY SURGERY.

It can not be denied that, in many of the paths that lead in the direction of progress, our brethren in the Western States leap where we of the East crawl. We have before had occasion to allude to this state of things as it concerns medicine, and have recognized the quickness of perception and the promptness of action which led to the establishment of the first school for the instruction of graduates in one of the Western cities. Our attention is now again drawn to the fact by the contents of a modest *brochure* entitled the "Proceedings of the First Three Meetings of the Surgeons of the Eastern Division of the Wabash, St. Louis & Pacific Railway." The three meetings were held, respectively, at Decatur, Ill., January 25, 1882, at Fort Wayne, Ind., June 4, 1883, and at Springfield, Ill., April 30, 1884. Although the proceedings at all these meetings are given within the compass of not many more than a hundred octavo pages, they include a number of papers of the very highest practical value, all treating of matters more or less closely connected with the care of persons injured in railway accidents. In another department of this issue of the "Journal" we give full abstracts of two of these papers, and should have been glad to give the substance of others of them but for the fact that our space was limited. As it is, we can only express the hope that a large enough edition of the "Proceedings" has been published to insure its coming into the possession of a great portion of the profession throughout the country, for we feel assured that no general practitioner who is at all likely to be called upon to render his professional aid in the class of injuries to which it is devoted—and there are but few indeed of our number who are exempt from such a liability—can fail to realize, after its perusal, that his hands have been strengthened.

It is well known to surgeons of large experience that, even from a strictly surgical point of view, railway injuries present features of marked contrast to those which, in every other respect than their cause, seem to the inexperienced to be their counterparts. When to this are added the complicating conditions involved in the shock almost if not altogether peculiar to them, and the frequent necessity of transporting the wounded under difficulties—both of which conditions are admirably treated of in the papers of which we give abstracts—it will readily be seen that railway surgery may be looked upon as in some sort a special branch of our art. That being the case, it is not easy to over-estimate the good to be accomplished by just such conferences as those held at the three meetings in question. The gentlemen who met on those occasions were the surgeons regularly employed by the company, or the associated system of companies, that controls and manages the railway

service of a vast territory; and, organized as they are, it would not be forcing an inference to conclude that they represented an amount of experience in railway injuries unapproached by that of many more than their own number of practitioners elsewhere.

We understand it to be the case that our more important railways here at the East have not wholly neglected to make something like a systematic provision for prompt and adequate medical service in emergencies, but we fear it must be admitted that in many instances an accident attended with the injury of passengers or employees brings up in the official mind little else than these two considerations: how to pack off the sufferers with all possible speed, and with little concern for their comfort and scant precautions to favor their ultimate recovery, to the nearest hospital; and how to give the facts in the case such an aspect as to throw obstacles in the way of a suit for damages. We are aware that one of our companies has done something in the way of furnishing its trains with a stock of the more ordinary surgical appliances, but we have no knowledge that in this part of the country there is any provision at all comparable to the organized medical service of the Wabash, St. Louis & Pacific Railway. Even if it is true, however, that "it pays better to transport hogs than men," as one of our railway magnates was once reported to have remarked, the time may not be far distant when passengers who have to choose between rival lines may take into account the relative advantages of being treated, in case of injury, as if they were of less importance than hogs, save for their constitutional right to sue, and, on the other hand, of meeting with the tenderness that is so heartily inculcated in the salutatory address of the president of the Surgical Association of the Wabash, St. Louis & Pacific Railway, Chief Surgeon J. T. Woods, of Toledo, Ohio.

It seems that Dr. Woods is to be credited with having conceived the idea of such a service, and with having persevered, in the face of no slight obstacles, to the final accomplishment of its organization. In the address to which we have alluded he gives an account of some of the difficulties with which he had to contend, and this feature of the address appears to us second only to the philanthropic spirit which pervades it. The first impediment that he had to overcome was the natural disinclination of a corporation organized for the purpose of money-making to engage in an undertaking involving an expense difficult to estimate, one that it was under no legal or other apparent obligation to engage in, and one that, it was feared, might lead to imposition and abuse. In the light of such considerations the company's hesitation certainly was not altogether irrational, especially when it was remembered that more or less system had been attempted elsewhere, but the work had proved so desultory and unsatisfactory, and finally so expensive, that, as Dr. Woods says, it had usually either gradually dropped to pieces or been suddenly abandoned, as was the case on the whole system controlled by Mr. Vanderbilt, in which the company now took no care of any one, and medical men who served the injured had to look to the patients for their pay—the maimed men who had not the means, however well disposed.

It is in the highest degree creditable, both to Dr. Woods and to the president of the Wabash, St. Louis & Pacific Railway, that these arguments were not long allowed to stand in the way of the project, but that an arrangement was agreed upon which recognized that "the quality of mercy" had a legitimate place even in business transactions. There can be no question that the loyalty of the employees has been strengthened by the successful working of the plan, and it is safe to assume, we think, that the stockholders' profits have not been lessened by it.

Among the other difficulties encountered by Dr. Woods was the distrust with which the employees at first looked upon the surgeons who were selected for the service—a feeling which can only be regarded as the natural expression of every man's preference for choosing his own doctor; but gradually as the men found that the surgeons had been appointed with great discrimination, and that their reputation was of the best in their respective communities, this feeling vanished. This result was due to the success with which another problem had been solved—that of selecting proper men to serve as surgeons to the line. Although a disposition was encountered in some quarters to introduce local professional animosities, Dr. Woods succeeded so well in this delicate part of his task that he was able to say in his address that he did not believe that, as a whole, better professional men had ever served an organization. Judging by the admirable papers which they read at the meetings, whether considered merely as contributions to the art of railway surgery, or regarded as tests of their devotion to the objects of the organization and to the broad claims of humanity, we can not entertain the slightest doubt that his words were justified, and we trust that his association will prove the parent of many others of the same sort.

MINOR PARAGRAPHS

ST. MARY'S GENERAL HOSPITAL, BROOKLYN.

THE first annual report of this institution, although only a pamphlet, contains a good example for the older hospitals in the fact that it makes a very creditable attempt at giving the reader some insight into the practice of the house, as shown in brief reports of cases, with comments, from the various special departments of the hospital, and in the statistical tables appended. The result is that the report is of interest to members of the profession in general. Within three months of the time the hospital opened its doors it was so unfortunate as to meet with evidence of the effects of sewer-gas on its patients, but it is gratifying to learn that the city authorities came promptly to the rescue, and that, the defective sewer connections having been remedied, there has been no further trouble on that score. Young as it is, having been in operation only since the close of the year 1882, the hospital seems remarkably well equipped, and gives promise of a high degree of usefulness, not only to the sick poor, but to the medical profession.

NEWS ITEMS, ETC.

Yellow Fever in Mexico.—Notwithstanding the occurrence of a few cases of the disease in Mazatlan during the months of May, June, and July, the sanitary officials of that port give clean bills of health to vessels touching there, and masters of steamers bound to American ports are therefore warned by the

Washington correspondents of the associated press to take proper precautions on calling at Mazatlan.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending August 12, 1884:

DISEASES.	Week ending Aug. 5.		Week ending Aug. 12.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	1	1	0	0
Typhoid Fever	22	6	24	7
Scarlet Fever	37	5	33	3
Cerebro-spinal meningitis	3	3	3	3
Measles	84	20	62	14
Diphtheria	26	9	26	13

Cholera.—The epidemic on the French Mediterranean shore has continued to decline during the week, and there seems reason to entertain the hope that it may not now overrun a great extent of country this season, although it has spread to several Italian towns.

Small-pox, according to the "Medical Times and Gazette," is reported to be prevailing to an alarming extent at the diamond-fields of South Africa.

The Canadian Medical Association is to hold its annual meeting in Montreal on Monday, Tuesday, and Wednesday, the 25th, 26th, and 27th inst. The "Union médicale du Canada" learns that the following-named papers are to be read: Burns and their Consequences, by Dr. Gardener, of London; Estlander's Operation, by Dr. Fulton, of Toronto; Myxo-sarcoma, by Dr. Oldright, of Toronto; Puerperal Septicæmia, by Dr. Campbell, of Seaforth; Naso-pharyngeal Catarrh, by Dr. Ryerson, of Toronto; Jequirity in Granular Ophthalmia, by Dr. Buller, of Montreal; Recent Progress in Abdominal Surgery, by Dr. Rosebrugh, of Hamilton; Pneumonia as an Infectious Disease, by Dr. Osler, of Montreal; Medical Advertising and Secret Remedies, by Dr. Dupuis, of Kingston; Materia Cogitans, by Dr. Howard, of Montreal; Cerebro-spinal Meningitis, by Dr. Harrison, of Selkirk; Opium-eating and its Treatment, by Dr. Tilt, of Guelph; and Modern Progress in Laryngology, by Dr. Major, of Montreal.

The International Medical Congress of 1887.—On Tuesday Dr. John S. Billings, of the army, tendered to the International Medical Congress, now in session in Copenhagen, an invitation to hold its meeting of 1887 in Washington.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 3, 1884, to August 9, 1884:*

GIBSON, J. R., Major and Surgeon. Granted leave of absence for one month and fifteen days. S. O. 36, Headquarters Division of the Atlantic, August 4, 1884.

HEIZMANN, C. L., Captain and Assistant Surgeon. Relieved from duty at Columbus Barracks, Ohio, and ordered for duty in Department of the East. Par. 2, S. O. 180, A. G. O., August 2, 1884.

MC CREERY, GEORGE, First Lieutenant and Assistant Surgeon. Leave of absence extended two months. Par. 4, S. O. 180, A. G. O., August 2, 1884.

HOPKINS, W. E., First Lieutenant and Assistant Surgeon. Granted one month's leave of absence, with permission to apply for one month's extension. Par. 1, S. O. 67, Headquarters Department of Arizona, August 1, 1884.

Society Meetings for the Coming Week:

MONDAY, August 18th: Chicago Medical Society (Adjourned Discussion on Cholera).

TUESDAY, August 19th: Lehigh Valley Medical Association

(Mauch Chunk, Pa.); Ogdensburg, N. Y., Medical Association.

WEDNESDAY, August 20th: New Jersey Academy of Medicine (Newark).

OBITUARY NOTES.

Sir Erasmus Wilson.—Last Saturday a cable dispatch to the newspapers announced the death of Sir Erasmus Wilson, F. R. S., the well-known dermatologist of London. Besides Professor Wilson's systematic treatise on diseases of the skin, which went through a number of editions, was republished in this country, and was the standard work on the subject in the English language for many years—up to the time when Hebra's brilliant teaching led to a widespread study of that branch of medicine *de novo* in Great Britain and America, as well as on the continent of Europe; besides that, he was the author of several monographs in dermatology, one of which, being somewhat of a popular character, made him widely known outside the ranks of the profession, while another, his "Lectures on Eczema," is the one by which perhaps the future historian of British dermatology will best judge of its author's true status. Professor Wilson will be remembered, too, in connection with the "Journal of Cutaneous Medicine and Diseases of the Skin," a quarterly periodical which was published from 1867 to 1871.

Although his influence as an authority in dermatology was much weakened by his persistent opposition—in the face of the plainest facts—to the theory of the parasitic origin of certain affections of the skin, his admirable clinical delineations, his undisputed diagnostic skill, and his originality and acuteness in therapeutics made him always respected by other workers in the same field. But it was not in dermatology alone that he made himself felt; his text-book of anatomy was for many years in general use among medical students in this country, until it was finally eclipsed by larger and more elaborate works.

Professor Wilson amassed a fortune by his practice as a specialist in skin diseases, and he used his means generously, giving pecuniary aid to needy charitable institutions on many occasions. He also founded the chair of dermatology at the Royal College of Surgeons, of which he himself was chosen to be the first occupant, and established a museum of dermatology in connection therewith. His public spirit and liberality overflowed into non-medical channels, as was well illustrated by his infusing life into the languid movement for conveying Cleopatra's needle from Alexandria to London, furnishing a great part of the money required for the undertaking, and by his own individual exertions contributing chiefly to the successful accomplishment of the enterprise.

Letters to the Editor.

MATERNAL IMPRESSIONS AND CONGENITAL MALFORMATIONS.

PEABODY, W. VA., July 12, 1884.

To the Editor of the New York Medical Journal:

SIR: On May 22d I was called to Mrs. Oliver A., and found her in labor. As I entered the room, she told me the child would be deformed. When questioned, she said she had been frightened at a negro with a "reel foot" about the end of the first month of pregnancy. In order to test her imagination, I asked her which foot, and she said the right one, and insisted that the child would be the same way. On making an exami-

nation, I found the head presenting and labor going on well, and I assured her that everything would soon be over. In about an hour she was delivered of a large male child, and, to my surprise, I found a *talipes varus* of the right foot.

May 23d I called, and found that the child had imperforate anus. Dr. Lonsbury was called, and an incision was made in the ano-perineal region to the depth of two inches, when, finding no traces of a rectum, we closed the opening and proposed Littré's operation, but, being denied, we abandoned it as hopeless. The next day I found the wound doing nicely and the child nursing well. On the 25th the child had two liquid stools through the urethra; it was nursing well and the wound was closing. The condition continued the same until the 2d of June, when peritonitis set in, and the child died June 4th.

Was the *talipes varus* due to the impression on the mother's mind? Was it merely accidental that the two deformities occurred in the same child?

LESTER KELLER, M. D.

AN ODD CASE.

FORT BENNETT, DAKOTA, August 3, 1884.

To the Editor of the New York Medical Journal:

SIR: I have been unable to find in the books at my disposal a case similar to the following. Is it unique? A soldier, aged twenty-four, appeared at sick-call complaining of "hiccougs." He said he had slept very little since midnight, and was "sore all over from hiccouging." He seemed to be suffering considerably. I questioned him closely, but was unable to find anything likely to cause the disturbance until it came out that he was constipated, and had been so "for more than a week." It seems that between "having something to do" and being too lazy he had neglected going to the "rear," except at very irregular intervals, for a long time. I gave him an active purge, and told him to give himself an injection of warm water and soap-suds, and not to delay going to the "rear" when nature warned him.

He appeared at surgeon's call next morning, and told me his bowels had moved freely the afternoon before, and that in a short time afterward "the hiccougs had left him."

Could "reflex action" (a delightful thing to hide behind) have been the cause? I have known of constipation producing neuralgic pains down the legs, but have never heard of its causing "hiccougs." Yours truly,

C. N. B. MACAULEY.

First Lieutenant and Assistant Surgeon, U. S. Army.

Proceedings of Societies.

NEW YORK OBSTETRICAL SOCIETY.

A STATED meeting was held April 1, 1884, W. M. FOLK, M. D., President, in the chair.

Dr. W. R. GILLETTE presented **A Metallic Catheter with a Terminal Opening**, which he had found a valuable substitute for Davidson's rubber catheter in certain cases in which the vesical mucous membrane was caught in the fenestra of the rubber instrument, producing a temporary cystitis.

Dr. GILLETTE also presented a specimen of **the Semen of the Elephant**, which was examined with the microscope.

Puerperal Eelampsia.—Dr. B. F. DAWSON read the following history of a case: "Mrs. S., thirty-seven years old, the mother of ten children, consulted me on the 14th of March, be-

ing then in the seventh month of pregnancy. She said that she had never 'felt life' during the existing pregnancy. At some previous labor she had suffered lacerations of the perineum and cervix, which were closed by myself about two years ago. The operations were followed by perfect relief from the symptoms and by this pregnancy. She had not been feeling well for some months, and on the 10th of March she was suddenly seized with a severe chill, and had fever and obstinate vomiting, with very scanty urine. She called in a physician, who told her that she was suffering from acute Bright's disease, and gave a very unfavorable prognosis. When I first saw her she was constantly retching, was unable to retain anything on her stomach, and showed on the face, neck, and arms an erythematous blush, accompanied by sore throat and reddening of the tongue. There was no oedema of the face or ankles, but there was slight pitting on pressure along the crests of the tibia, with a varicose condition of the veins of the legs. There was no headache, stupor, or disturbance of vision. The bowels were constipated. I gave her five grains of calomel, to be followed by a saline cathartic, and requested a specimen of the urine to be sent for examination.

"The next day Dr. Hawley examined the urine, and found little abnormal about it. The blush was not now so marked, but the throat and tongue were in the same condition as before, and the nausea was still intense. She had passed two fluid-ounces of urine during the preceding twenty-four hours, and it contained about fifty per cent. of albumin. I gave her a grain and a half of elaterium, in divided doses.

"On the following day she had passed no urine, and the bowels had not moved. A catheter was introduced, and one drop of dark urine was brought out in the instrument. Infusion of digitalis was given by the rectum, in doses of half a fluid-ounce, and drachm doses of fluid extract of jaborandi were also administered.

"On the following day she had had a small, semi-solid movement from the bowels, but no passage of urine. The catheter was again passed, but with a negative result. The pulse was 102, the temperature normal. There was no headache, disturbance of vision, or oedema, but the nausea and vomiting were constant, and the throat was swollen and sore. Three drops of croton-oil were given, cups were applied to the loins, and the patient was kept in a hot-air bath for the whole night.

"The next morning she was feeling better, but had passed no urine, and her bowels had not moved, nor had any perspiration been induced by the hot-air bath. About a fluidrachm of dark urine was drawn with the catheter. She was now suffering from cramps in the legs and arms. The digitalis and jaborandi were continued, and she was quieted with small hypodermic injections of morphine.

"On the succeeding morning she was suddenly delivered of a dead child, apparently of about seven months and a half. There was no hæmorrhage, and the uterus was well contracted. She had passed a small amount of urine, and felt much better. Still there were no marked symptoms of uræmia. The hot-air bath was repeated at night.

"On the following day, one week from the time when she was first seen, she was found stupid and slightly delirious. The rectal temperature was 105° F. There was no odor to the vaginal discharge. The vagina and rectum were washed out with a solution of bichloride of mercury, 1-2,000, and about a fluidrachm of urine was withdrawn with the catheter. At noon she had a slight tonic spasm, and quietly died. An autopsy was not allowed."

Dr. Dawson added that the chief interest of the case related to the absence of any of the usual marked symptoms of uræmia until near the close of life, notwithstanding there had been

almost complete suppression of urine during the nine days of the patient's sickness. She had remained perfectly rational, and said she felt well, with the exception of nausea, up to just before death. The case would have been less remarkable had there been any vicarious action on the part of the alimentary canal or the skin. There was but very little material vomited, and it was impossible to make the skin and rectum act.

The PRESIDENT said the case presented many features in common with one which he narrated at the society about two years ago. He referred to the case in which by mistake he removed the only kidney. In that instance, however, the stomach and the intestine seemed to take up the work of the absent kidney, and, after the third or fourth day, the patient began to have about three very copious fluid discharges from the rectum every twenty-four hours, and vomited as many as five or six times during the same period, the vomited matters containing a large amount of urea. Her mind remained perfectly clear up to within twenty-four hours of death. She died, as Dr. Dawson's patient did, while in a light convulsion, this being the only convulsion which she had during the eleven days of her life after removal of the kidney. He believed a number of cases had been reported in which children had lived several days, perhaps as many as fifteen, with entire suppression of urine.

Dr. GILLETTE had treated a child which had total suppression of urine for more than ten days, following scarlatina. The child had a strongly uræmic odor, but nothing passed by the rectum. It finally died suddenly, having been perfectly clear in mind up to a moment before death. He had also seen a case in consultation in which there had been complete suppression of urine for over two weeks. An autopsy was made, and pyonephrosis was found in a marked degree in both kidneys.

Rupture of the Repaired Perineum at subsequent Confinements.—Dr. H. F. WALKER said that within two months past he had attended three women, multipara, each of whom had renewed rupture of the perineum. The first patient had had three children, and he had attended her in her first and third confinements. There was rupture of the perineum at the first confinement, which he repaired immediately. The second time she was delivered in Philadelphia. The physician who attended her closed a rupture of the perineum, and it healed by first intention. The third child was born about six weeks ago, and again there was rupture. In the two other cases two children had been borne, Dr. Walker having attended one of the patients in both confinements, and the other only in her last. In both there had been rupture of the perineum at the first confinement, which was closed, and again rupture and closure at the second confinement, the operation on each occasion being attended with success. He inquired whether it had been the experience of other members to have to repeat perineorrhaphy.

Dr. J. B. HUNTER had repaired a rupture through the sphincter ani in one case, and only slight laceration took place at a subsequent labor, the sphincter remaining perfect. In three other instances he had avoided renewed laceration at confinements by retarding the progress of the head, but the perineum was not left so strong as before labor.

Dr. C. MACKENZIE had seen one lady who had had rupture of the perineum at three successive confinements. The perineum was of that dark brown color which had been said to indicate want of proper elasticity. The lesion seemed not to occur each time in the same place. Repair had been effected without difficulty.

Dr. H. J. GARRIGUES had attended a very blonde lady in three confinements. In the first two a laceration of the perineum occurred, which healed entirely after primary operation; in the third no rupture took place, although the child was as large as the others had been, if not larger.

The PRESIDENT had recently attended a woman who was first confined about twelve months before. On both occasions there was rupture of the perineum followed by successful repair. The second rupture was not exactly in the line of the first. It might not be inappropriate to say a word in this connection about a method which he had been accustomed to employ for the prevention of rupture of the perineum. It was not new, but he did not think it had been described in a perfectly plain manner, or in such a way as to attract the attention of the reader. The method consisted in the prevention of extension of the head until the suboccipital region pressed well up against the arch of the pubes. By thus bringing the suboccipital region squarely up against the pubic arch before allowing extension to take place, we could cause the shorter diameters of the head to be presented as it passed through the osium vaginae, relieving the perineum of pressure proportionately.

Dr. GILLETTE had practiced this method a good while, and had found it of great benefit in the prevention of rupture of the perineum.

Dr. HUNTER said that this method had been taught years ago by Dr. Thomas, but that he (Dr. Hunter) had found it difficult to put in practice. It was not an easy matter to take hold of the head at any point and regulate the direction of its diameters. He had found the most safety to lie in retarding the progress of the head by making pressure on it or on the perineum.

The PRESIDENT thought this amounted to the same thing as the procedure of which he spoke.

Dr. WALKER had found more lacerations occur from the passage of the shoulders than from that of the head.

The PRESIDENT corroborated this statement, but said that, according to his observation, when the perineum was lacerated by the passage of the shoulders there was previously a nick in the posterior vaginal wall, which the shoulders plowed through and enlarged. In reply to a question by Dr. Mackenzie, he said that, according to the method to which he referred, pressure was made on the forehead, flexing the head, resisting extension, and thereby forcing the occiput out of the osium vaginae before permitting extension to occur.

Large Ovarian Cyst.—Dr. HUNTER presented a specimen which had been removed that day. The patient was thirty-four years of age. Four years ago she noticed some enlargement of the abdomen, which within the last year had increased rapidly. Dr. Hunter saw her for the first time a week ago, when he found the abdomen enormously distended by an ovarian tumor. It was a question at first, however, whether the distension was due to ascites or to a cystic tumor. On making an abdominal section, he found the sac everywhere adherent in its upper part to the abdominal walls and to the intestines. The cyst was evacuated and then enucleated, but, when the lower half was reached, it was found to be non-adherent. A small portion had to be cut away and the pedicle tied. The main pedicle was also tied and dropped back. The entire cyst, sac and contents, weighed fifty-five pounds. It was multilocular, but the larger portion of it consisted of a single cyst. The fluid was dark straw-colored. There was some oozing, and a few points were tied, but all bleeding had ceased when the abdominal wound was closed. No drainage-tube was inserted. That evening the patient was doing well. The peculiarity of the case was that the upper portion of the tumor was firmly adherent, while the lower half was free. Had this fact been known beforehand, he did not know that the operation could have been done differently.

Note by Dr. Hunter, April 14th.—The patient made a good recovery, having had no bad symptoms whatever.

Puerperal Eclampsia.—Dr. GARRIGUES read the history of a case:

The patient was twenty-one years old, unmarried, pregnant

for the second time. After her first confinement, three years before, she had been insane for two years. Besides enormous oedema, there was hyperæsthesia of a great part of the skin. The urine contained forty-five per cent. of albumin and many granular and hyaline casts. She had violent headache. She had two attacks of eclampsia. Eight ounces of blood were withdrawn, and a drachm of chloral hydrate was injected into the rectum. The external os formed a transverse slit just admitting the tips of two fingers. She was put under the influence of chloroform, the os was dilated with Barnes's dilators without any difficulty, and a living male child weighing seven pounds and eleven ounces was extracted by turning. After delivery she had one more convulsion. The following days she was treated with the hot pack and derivatives over the kidneys and bowels, and made an excellent recovery, except that her insanity reappeared in the form of melancholia with fits of violence.

He reported the case because several authorities deprecated artificial dilatation and turning, stating that it made the convulsions worse, but he thought this teaching was a relic from the times preceding the discovery of anæsthetics.

Dr. W. M. CHAMBERLAIN said that, in a case of his, the eclamptic phenomena ceased as soon as dilatation of the cervix was accomplished, although delivery was not complete until seven hours later. Since then he had seen another case in consultation. He performed *accouchement forcé*, and in this instance also there were no convulsions after dilatation was considerably advanced until several hours after delivery was effected. This constituted his third case in which convulsions were recurring with considerable frequency up to the time when dilatation was secured, were then suspended until after delivery, and came on again apparently with post-partum contraction of the uterus. Two of the patients recovered; the third one died.

Dr. MACKENZIE inquired whether the patients became conscious when dilatation was effected.

Dr. CHAMBERLAIN replied that the convulsions ceased, but the comatose condition continued.

Dr. GILLETTE did not know but the observation made was an important one, namely, that puerperal convulsions ceased with dilatation of the cervix. He had seen a number of such cases, but, on the other hand, on several occasions he had practiced *accouchement forcé* with the result of intensifying the convulsions. He remembered distinctly one case in which he found the patient suffering from profound coma. Labor had just begun, and the os was dilated but very little. He effected rapid dilatation, but the convulsions continued. He could not see that delivery had any effect whatever in moderating the convulsions. The patient lived forty-eight hours. There was complete suppression of urine. He did not think there was any general rule which would cover all cases. Each case must be a law unto itself. Undoubtedly some cases were aggravated by the mechanical process of dilating the cervix. When dilatation was effected, no doubt some of the reflex irritation was removed, but he did not think that, from the observations thus far made, any proposition could be shaped regulating the management of all cases. There was scarcely any condition, unless it was placenta previa, in which there was so great a scope for the display of ingenuity as in eclampsia with commencing labor. It was perhaps the disposition of every one in such cases to hasten delivery, and yet he believed he had done injury in some instances by interfering.

HENRY J. GARRIGUES, M. D.,

B. F. DAWSON, M. D.,

FRANK P. FOSTER, M. D., *ex officio*,

Committee on Publication.

CHICAGO MEDICAL SOCIETY.

*Meeting of August 4, 1884.***The Ætiology, Pathology, and Treatment of Cholera.**—

The discussion of this subject was opened by Dr. J. H. EMBIDGE with a paper on the *treatment* of the disease.

The treatment of cholera to-day, he stated, was changed but very little from what it was sixty years ago. Innumerable attempts had been made to change and improve it, but all to little or no purpose. Better than in any other way, perhaps, an idea could be given of recent efforts at improving cholera remedies by recalling the treatment of threescore years ago, and afterward giving briefly an enumeration of the various additions recommended from epidemic to epidemic.

Calomel certainly came first in order, and, when employed in proper doses, together with opium, and more particularly in the early stage of the disease, seemed to be equally effective among natives as venesection was among Europeans in arresting its progress. The plan of treatment alluded to was to administer twenty grains of calomel and wash it down with sixty drops of laudanum and twenty drops of oil of peppermint in two ounces of water; and to support the warmth by external heat, the hot bath and hot friction, and internally by cordials. Thus wrote Dr. James Johnson in 1824, in his classical work on "Tropical Diseases."

The discussion at this meeting would indicate how much substantial progress had been made beyond that of sixty years ago, for then the idea seemed to be "to start the bile," as the expression was, and afterward to quiet with opium and support the powers of life. Were we much in advance of this treatment in 1884?

The epidemics succeeding 1817 seemed to call out the following remedial agents, of none of which had he found mention made prior to the dates accompanying them. The mere enumeration of them would suffice to show how lamentably fatal cholera had been, and how helpless medical skill was in rescuing human life from this scourge. Many remedies that we now saw heralded in print as new, and wonderful in curing cholera, were very old. Many remedial measures mentioned in the lists to follow would provoke a smile of pity or of incredulity.

The epidemic of 1826-'27 called out the following-named agents as useful in curing cholera: Carbolic acid, hydrocyanic acid, nitro-muriatic acid, alum, antimony, arnica, bismuth, buchu, cauterization, chlorine, counter-irritation, cupping, enemata of cold water, gold chloride, oxygen, purgatives, sodium chloride.

The epidemic of 1832-'34 brought out the following-named remedies, a lengthy list, perhaps explained by the fact that the epidemic was terrible in its severity and mortality: Sulphuric acid, albumen, alkalies, ammonia, bandaging, hot-air baths, nitric-acid baths, sand baths, vapor baths, belladonna, bile, bladder injections, blood transfusion, cinchona, coffee, Colombo, copper sulphate, creasote, diuretics, electricity, evacuates, narcotic enemata, saline enemata, tobacco enemata, guaco, hæmostatics, horse-radish, ice, inhalations, venous saline injections, ipecac, iron, juniper-berry oil, lead, ligature, lime-water, venous milk injections, musk, nitrous oxide, oil of cajuput, croton-oil, percussion (tapping the abdomen), salines, stimulants, strychnine, sudorifics, the tourniquet, turpentine, cold water.

In 1848 the following remedies were brought forward: Hydrochloric acid, anesthetics, arsenic, camphor, capsicum, carbon disulphide, carbon chloride, chloroform, ergot, ether, gunpowder, hydrotherapy, matico, metals, naphtha, naphthaline, silver nitrate, silver oxide, sulphur, zinc oxide, zinc valerianate.

The epidemic of 1854 brought out the following-named remedies: Alcohol, calcium-chloride bathis, castor-oil, hard cider, cinnamon-oil, eupatorium, garlic, movement, potassium permanganate, quassia, sugar, vaccination, water by injection into the peritoneal cavity.

Dr. I. N. DANFORTH gave the pathology of cholera from study and from his own researches, and stated that he knew enough about it to say that he knew but little regarding its causation. He had studied the disease carefully in 1873, and illustrated his remarks by microscopic specimens that he mounted at that time. Every organ of the body was more or less affected by the disease. There were three lesions that were apparently always present—in the blood, in the intestinal canal, and in the kidneys. The blood in the early stage became thickened, it might not flow, and sometimes was stationary; it was invaded with microbes, or micrococci, or a bacillus, but these organisms were not related to the causation of cholera. The same variety was not always found in the blood, in the intestinal canal, or in the discharges; cholera was not produced by any specific germ. The blood lost its watery element to a great extent, and with great rapidity. During the localized epidemic of 1873 he had examined the discharges from the intestinal canal in ante-mortem and in post-mortem specimens. In each they contained vast numbers of bacteria, micrococci, and other things, but he would assert that these had nothing to do with the causation of cholera, but that a nidus existed for their development. Ziegler, Lebert, and others, according to von Ziemssen, had stated the same thing, that they were incidentally there, that they sprang up in the intestinal fluid. It was a field for them.

The first slide shown represented a drawing the speaker had made illustrating the disease at about the middle of the attack, and showed a grouping of cells and of granular matter. Some authors stated that the intestinal epithelial cells were not discharged until after death, but he was sure that while the patient was living the intestine might be stripped of its epithelial coating. A specimen from the ileum, about ten inches above the valve, was shown, to illustrate the cellular coating of one of the villi. Specimens of Peyer's glands were shown, in a distended form, also to show a grouping of cells and many nuclei. The entire surface of the lining of the bowel was very red, or bright pink, or there were ecchymotic patches. The arteries were not much distended, but there was an enormous amount of stagnant blood in the intestinal canal. The kidneys underwent a rapid fatty change in the early stage, the cortical portion becoming enlarged, but this acute fatty change rarely became chronic after recovery. The liver, spleen, brain, spinal cord, and nervous system sometimes became hyperæmic. The speaker did not pretend to say that his remarks gave additional light upon the causes of cholera. We had not arrived at the cause. Lebert had said that there was a specific cholera germ, but he had not stated what it was. Ziegler said that we did not know it. Skoda also stated that a germ was present as the cause. Koch believed he had discovered the germs, but his experiments to produce the disease in domestic animals had proved futile, perhaps, though, for the reason that, as was well known, they did not take cholera. There were certain changes that occurred in the small intestine, due to the invasion of specific germs or of a virus that we do not know, the effects of which determined to the emunctory organs and effected depuration.

Dr. W. T. BELFIELD, being requested to give his views upon the pathology, stated that he never had seen an epidemic of the disease, and his knowledge of it was second-hand. He would briefly endeavor to recapitulate Dr. Koch's discoveries regarding the disease as it occurred in Egypt and India. There were constantly present in the wall of the intestine organisms that

were easily recognized by reagents and staining tests. These organisms, called bacilli, were never found in the blood or in any of the organs affected by other diseases. This did not prove that these organisms caused cholera, or that their relation was the same as that of the organisms found in one or two other infectious diseases to be named presently. The association of these bacilli was explained in one or two or three ways: They might be a cause, but he thought the reverse was the case. To decide this, it would be necessary to separate the organism from the juices, and inoculate a healthy animal, as we would in anthrax. Koch had stated that this kind of organism, and no other, was constantly associated with cholera. He had made crucial tests, but all the attempts to inoculate dogs, cats, and rabbits had proved futile. This, however, did not prove either that the germ did or did not cause cholera. Certain domestic animals were insusceptible to cholera. The bacillus was asserted by Koch to be always present and to multiply rapidly. In relapsing fever low organisms were found. The spirillum was always present in the acme of that disease, but that did not prove it to be the cause of the disease. If human beings could be experimented upon in relation to the connection of the bacillus with the cause of cholera, and a person thus contracted it, then this theory could not be contradicted. The bacillus flourished in slightly alkaline fluid, and acids destroyed it, and had the best effect in treatment.

Dr. JOHN BARTLETT stated that in 1874 he made observations on a fungus and concluded that this fungus underwent phases of development. First it was a cell. It was the active agent in altering and impairing the blood and tissues. This we supposed was ultimate. In ague it was a cell in a developing fluid, and did not remain at rest. It emigrated and found its way into a tissue. These cells formed a certain crystalline something. This crystalline substance was not lifeless; it put forth buds, and these sent forth a fluid, which was homogeneous and protoplasmic. The cells might be inert and not self-multiplying. The protoplasmic fluid was not recognized in the blood. Protoplasmic fluid was not recognizable by the microscope until cells were developed. Dr. Koch never had demonstrated them so as to be visible to the naked eye, and his results were unsatisfactory.

Dr. C. G. SMITH had made up his mind years ago that the disease was highly contagious, yet there were many points to be settled relative to the contagiousness of cholera. A woman of Florence Nightingale's experience pronounced against this theory, and some physicians professed to have disproved it, saying that doctors need take no special precaution to guard against contracting the disease.

The enthusiasm of some French authorities was so great against the theory of contagiousness that they had been known to taste the discharges of a cholera patient—and they did not take the disease either. Now, regarding this, it had been said that the discharges, when fresh, were not contagious; they must ferment or decompose before they became contagious. The whole history of the disease proved its communicability. In 1854 especially was this true. In India it was propagated by moisture and filth, and then it followed the great lines of travel, but it did not go quite around the world. He had never heard of its being in Australia. It could be stamped or wiped out, and this had been done, as had been proved, by vigorous executive methods of quarantine before it reached this continent. If it got a foothold here, it would be more difficult to check its course along the railroad lines of travel. Yet it could, in a proper way, be wiped out. During the last epidemic in this city there seemed to be a focus of cholera at Butterfield and Thirtieth Streets. Twenty cases appeared suddenly, when the houses were fumigated, the people removed, and other vigorous measures

taken to purify the premises. This stamped it out. It was a malignant poison, and found its way into the intestines. Nature made an effort to remove this, by an eruptive process, so to speak, in pouring out serum from the blood, profuse perspiration, and other morbid symptoms, as a result of this purifying method. It had a paralyzing effect, the blood became thickened, there was want of secretion by the kidneys, cramps came on, and the other attendant symptoms—all arising from the loss of serum.

Dr. C. W. EARLE stated that men of his age had not yet passed through an epidemic of cholera. If it were germane to the subject under discussion, he would state the differentiation of infantile diseases. The summer bowel affections of children could, at a meeting of this society at an early date, be discussed. This, he thought, should concern us more at present than Asiatic cholera. Were the latter disease among us, then both could be better coped with and discussed simultaneously. Steps should be taken to diminish the great mortality among this young class, and at a future time, if desired, he would present his views upon that topic.

Dr. N. S. DAVIS was invited to give the differential diagnosis and treatment of cholera and cholera morbus. He stated that he felt embarrassed to attempt to discuss these subjects before the society, for the time was limited, and he feared that he would consume more time than belonged to him, and thus he could not do justice to the subject, and the result would be unsatisfactory to himself and others.

The following, in brief, had been his experience: He had studied cholera in its epidemic form clinically, in a degree, upon a number of occasions. In the summer of 1849, in the city of New York, he remained until the epidemic subsided, working night and day consecutively for twenty-one days, attending to those afflicted. In the autumn of 1849 he came to live in Chicago and treated the disease in this city, and in the summers of 1850, '51, and '52 also. In the summer of 1853 we were free from the disease; there was no semblance of it whatever. In 1854, between the 20th and the 24th of April, the people of this city awoke to find it again among them, and for a while a disjointed case would spring up every three, four, five, or six days during the months of May and June, although during the last days of June eight or ten deaths a day occurred. Dr. Davis then gave a number of reminiscences of quarantine along the Illinois River to prevent the disease from entering Chicago by preventing its coming from the interior of the State. In 1866 he pushed his last resources and nearly exhausted his powers of vision to discover the power of its contagion. He kept the discharges of patients for one or two weeks, and examined them microscopically. So far as cholera was concerned, there were half a dozen different varieties of germs that were accompaniments of the disease. And every variety of disease invested with a degenerative accumulation of the natural cells in the tissues was accompanied by some form of germs, which were deteriorated living organic matter, and reached dissolution, no matter what the disease was—not as a cause, but as an accompaniment. They were uniform and an accompaniment of effects. Experiments at inoculation might produce the disease. Some persons, perhaps, might have produced it in this manner. During the cholera of 1866, steamships crossed the ocean in nearly as short a time as they did now. It did not come with the tide of travel then. In 1848 it spread over Europe. He remembered two vessels that landed here that year—one at New Orleans, the other at New York. The former was not quarantined; the latter vessel arrived at New York, and two or three emigrants were attacked with cholera. They were taken to a boarding- or lodging-house on Washington Street, New York, where there were four hun-

dred people, yet cholera did not spread among them. This occurred in November or December. The vessel was quarantined, and the disease died out. At New Orleans the ship was not quarantined, and cholera developed furiously. In the spring of 1849 cholera started again in New York, spread over the country, and the disease died out. Of course, we looked to it, and tried to stamp it out. It rarely prevailed for more than one or two seasons successively, although in this city the years 1849, 1850, 1851, and 1852 had proved exceptions.

Regarding the theory of germs and the propagation of the disease: In 1854, in this city, no one disinfected the discharges, and we had no return of the disease until 1866. But, of course, this did not argue we should not do something toward placing ourselves in the best possible sanitary condition, for the disease could not flourish where cleanliness, good air, and pure water were found. During this year many timid people left the city. Some physicians also got away—and he advised any physician that was afraid of cholera to make his arrangements to get away from it. It began the latter part of June, but not very vigorously; deaths from it occurred every day in June and July. In August it rained nearly every day, and excessive moisture did not contribute toward supporting it. The result was, cholera entirely disappeared. During the early part of September the agriculturists held their State fair here; farmers that arrived in the city and stopped at hotels where but a few weeks previously people had died of cholera, all returned home safe. Yet during the last two weeks of September we had sultry weather. The water and moisture had all dried. Cholera again sprang up rapidly, and, in the three weeks in which it prevailed—reaching over into October—a thousand deaths occurred from it. Then we had frost, and a little later snow fell, and in another week no semblance of cholera was left.

Three things were essential to produce cholera: 1. High temperature; 2. A location where the soil was damp and favorable to decomposition of organic matter; 3. The presence of an organism or organic matter in that soil. In the rugged, hilly districts, where there was pure air, the disease could not spread. As an instance of proof of this, the Catskill Mountains were mentioned. The prevention included antiseptic measures and entire cleanliness. Alluvial soil must be looked after. Referring to the latter, particular mention was made of our own locality. The banks of portions of our rivers should be looked to.

Some points may be mentioned relative to the differentiation of epidemic cholera and cholera morbus, although the textbooks gave them. In the latter disease the urine was seldom or never suppressed; there was more griping in cholera morbus in its early stage; there was no preceding stage of diarrhoea in cholera morbus. In epidemic cholera there was usually a premonitory stage of diarrhoea lasting from four or five hours to as many days. It was a painless diarrhoea. There was lassitude, and sometimes a feeling of "crawling" was present, or a sense of numbness; then there supervened a strange prickly feeling, noises in the ears, or a stunning feeling in the head. Then the patient would pour out a vast quantity into the chamber, the blood would recede from the surface, he attempted to lie down, and vomiting would set in; and every ten to twenty minutes he would go through this process of vomiting and purging, discharging unusual quantities of serum. It was rice-colored or turbid in color. There were flocculi in the discharges, also mucous epithelium, which settled to the bottom. The patient gradually withered, the lips became leadened, he might have three or four more evacuations before cramps appeared, which occurred first in the calves, then in the muscles of the arms. His voice became husky or hoarse, and he was scarcely able to speak above a whisper. There was no bile in the discharges. There was lowering of the temperature; the breath was cool

before collapse and death. Sometimes cholera morbus would put on this aspect, and we might not be able to be absolutely certain of its nature, except that it was not epidemic cholera; and sometimes cholera would differ from the brief description he had given. A patient might be stricken suddenly, become faint, and go into collapse in from three to six hours, with perhaps only one evacuation of the bowels. The vital forces were at once paralyzed. The speaker then cited a typical case of this variety.

In regard to the indications for treatment, as soon as possible put a patient entirely at rest in the horizontal position. Give him some of the mineral acids, such as dilute sulphuric, or sulphurous acid, or hydrobromic acid. But we must not depend wholly on these to arrest the progress of the disease. The mucous membrane in its entirety was an absorbing surface; first its middle portion, as the stomach, became changed; it was converted into a most rapid exudation. The action of the stomach was exosmotic, while there was relaxation of the cutaneous surface. The blood, which underwent the rapid change as a result of the disease in the loss of its saline elements, was washed away. Great as the molecular change was, the heat ceased. The vaso-motor nerves might be the first to be acted on. We must attempt to stop the inverted action in the mucous membrane. How could it be done? He had cupped the spine, applied sinapisms over the epigastrium and between the shoulders, applied dry warmth, and used frictions. He had seen patients wrapped in ice-cold blankets, also ice and salt applied. He had used emetics of salt and mustard, and bled patients, and it had temporarily relieved them, but the blood would not always flow when a vein was opened. In a few instances he had seen emetics of mustard used with benefit. He had tried almost all rational measures, but had not tried vaccination nor horse-radish, as the paper of the evening stated had been used long ago.

The treatment that was most successful was to diminish the excitability of the mucous membrane, lessen the alvine discharges, and keep up the action of the kidneys. As above stated, he put the cholera patient at rest in a horizontal position, then applied dry warmth to his limbs. If cramps came on, he seized the muscles with his hands and compressed them, applied a large sinapism over the epigastrium, then, when it became too irritating, he changed its situation. The internal treatment was as follows: For both vomiting and purging he gave calomel gr. j, morphine gr. $\frac{1}{4}$, white sugar gr. v. After each attack of vomiting, mix it with a spoonful of ice-water, or drop it on the back part of the tongue, and let the patient swallow small pieces of ice afterward. Repeat this, perhaps, as often as every half hour or hour. Serve the rectum in the same manner with anodyne and alterative remedies, as acetate of lead gr. x, morphine gr. ss., in two ounces of cold water, aiding the patient to retain the enema. In 1866 he began using the following: \mathcal{R} Carbolic acid, gr. $\frac{1}{4}$ – $\frac{1}{2}$; paregoric, f 3 ss.; tincture of gelsemium, \mathfrak{m} v, in a little glycerin and water. Give these remedies in the proportions suggested alternately with the powders. He had found these means to be very beneficial in overcoming the vomiting and purging, and aiding the urinary secretion. We should replenish the system by administering beef-tea or other broths well seasoned with salt in suitable amount every fifteen minutes to supply the waste of saline elements from the blood. Give also strong coffee, a teaspoonful at a time, gradually increasing the nourishment to support the vaso-motor system. To check the profuse perspiration, give a hypodermic injection of atropine, and minute doses of strychnine, to act on the periphery. He would advise copious injections of saline solutions into the areolar tissues of the thigh, or any other part, until reaction came on.

Such, in brief, was the outline of treatment that Dr. Davis gave, and he concluded by saying that the chances were fair that in twenty-four hours the patient would be safe.

The society thanked Dr. Davis for his address, and it was resolved to continue the discussion of cholera at the meeting two weeks hence.

LISTON H. MONTGOMERY, M. D., *Secretary*.

Miscellany.

THERAPEUTICAL NOTES.

A Saline Intra-venous Injection for the Treatment of Cholera.—M. Hayem ("Revue scientifique"; "Lyon médical") thinks that, besides the need of restoring the salts lost from the blood of cholera patients, it is desirable to overcome its acidity, and for that reason he advises the addition of soda to the saline injection employed, as in the following formula:

Water.....	1,000 grammes;
Chloride of sodium.....	5 "
Hydrate of sodium.....	1 gramme;
Sulphate of sodium.....	25 grammes.

Copper and Cholera.—M. Burq has renewed his advocacy of copper by writing a note which was presented to the French *Académie des sciences* at a recent meeting by M. Bouley ("Gaz. hebd. de méd. et de chir."). The note contains the following propositions:

1. Persons imbued with copper by working with the metal daily have always been exempt from cholera, with very rare exceptions.

2. Numerous experiments in certain hospital services have demonstrated that the free use of copper is sovereign against the cramps and other nervous phenomena peculiar to cholera.

3. Dr. Lisle's cases (twenty-five cures in thirty-two cases), Dr. Pelletier's, Dr. Arnal's, Dr. Blondet's, Dr. Berger's, and those of others, as well as M. Burq's own experiments made at the Hôtel-Dieu in 1866, in conjunction with M. Horteloup, showed that the salts of copper, administered freely by the mouth and by the rectum, and by the endermic method in the gravest cases, were the remedy *par excellence* for cholera. Of sixty-six known cases of confirmed cholera, eighteen of which were treated at the Hôtel-Dieu, in which the absorption of the remedy was still possible, there were fifty-five recoveries.

[At a meeting of the *Société de biologie* (*Ibid.*), M. Bochefontaine submitted a letter from Dr. Muston, of Montbéliard, contradicting certain of M. Burq's assertions relative to cupric immunity from cholera, and stating that the workmen of Beaucourt, composing nearly the whole of the population, all work in copper, brass, iron, and steel, and that they were decimated by the epidemic of 1854, although they were the very workmen that M. Burq has declared were preserved from the disease.]

Borax as a Preventive of Cholera.—At the same meeting (*Ibid.*) M. de Cyon called attention anew to the antiseptic properties of borax, and to the fact that it was so harmless that it could be taken into the system in quantities as great as fifteen grammes [nearly half an ounce] daily without giving rise to the least trouble, as he had announced so long ago as 1878. Since that time his confidence has but increased in the excellent qualities of the drug in all parasitic or microbic affections, and notably as a powerful preservative against cholera. Its efficiency, he says, is shown by the fact that during past epidemics of cholera the workmen employed in manufactories of boric acid have always been spared, although the neighboring population were killed in the proportion of one third, as at Lordeveilo, in Italy, for instance, in 1864-'65. Taken in doses of five or six grammes daily, borax not only has a direct action on the microbes contained in the intestinal canal, but, passing into the blood, it is capable of reaching the bacilli which have gained access to that fluid. In cholera times the constipating action of the bi-borate of sodium is an additional argument in its favor. The author advises washing the surface of the body and the external mucous mem-

branes with a solution of boric acid or of borax, and mixing the latter with the food and drink to the extent of ten grammes in twenty-four hours.

The Use of Arsenic in Pulmonary Tuberculosis.—According to the "Centralblatt für klinische Medicin," Stintzing has tried the arsenic treatment at von Ziemssen's clinic in sixteen cases, two of which have proved fatal. In one of these cases the drug could be employed only for eleven days, and in the other only for three weeks. In but four cases was there any noticeable lowering of the temperature; in eight it was entirely unaffected; and in one case the drug even seemed to raise it. In three cases there had been no fever. In only one instance was there any diminution of the dyspnea, of the cough, or of the expectoration. The frequency of the pulse was maintained in four cases, increased in six, and decreased in two. Nutrition was not increased in a single instance; the weight of the body remained the same in two cases, and sank in nine, while two cases of apparent gain were accounted for by a highly dropsical condition. In no case was there a subsidence of the local processes in the lungs, but in eleven they advanced notably. The breathing capacity was repeatedly measured in twelve cases; four of the patients improved a little in this respect, but this did not seem very certain, for, on account of the patients' awkwardness, the early measurements were thought to have been too low; in two cases the capacity remained the same; and in six it was evidently diminished. The number of bacilli found was unaffected in seven cases, and increased in three; in only one was it diminished, and that several weeks after the use of the remedy had been discontinued.

The Transportation of Persons Injured in Railway Accidents.

At the first meeting of the Surgeons of the Eastern Division of the Wabash, St. Louis, and Pacific Railway, held at Decatur, Ill., in January, 1882, the president of the organization, Dr. J. T. Woods, of Toledo, O., who may be said also to have been the originator of the system of railway medical service now in operation, read a paper in which he said that, in its strictest sense, the duty of the medical man was humanitarian. His highest function was to preserve life, and next to that, to save from suffering. This was especially true of the surgeon whose path of duty led directly to the sufferer, and rudeness, indifference to humanity, and the omission of any possible means of alleviating suffering were wholly inexcusable. In actual practice the means of alleviation were not always apparent or easy of attainment, but still they were worthy of the most earnest inquiry and careful effort. It was not always in great and showy ways that we were to do the most actual good to those who fell under our care; but little things, the veriest trifles professionally considered, were often of mammoth proportions to the sufferer, and he was the only one to be considered. Our duty to a patient began at the moment of our arrival, and everything thereafter should be directed with scrupulous care, for every twinge of pain was a blow at life. For this reason both patients and surgeons were thankful for anaesthetics, and the former was relatively as grateful for avoidance of the dread agony in every step preparatory to the operative work proper.

These reflections had prompted him to present some suggestions in relation to the handling and transporting of the injured, both before and after operation. The ideas were to some extent applicable wherever bodily suffering was combined with the necessity of removal, but he desired to call attention to the injuries incident to railway accidents. Few rules or specific directions could be laid down, as conditions in every way varied, yet reflection and suggestions might prepare us to more readily and effectually do the duty of a special observer.

Whether the accident involved few or many, the surgeon usually arrived after the lapse of some time, during which interval much had been done as seemed best to those present; but on the arrival of a medical man he became the director of every movement, and with discretion could conduct future proceedings much as in his judgment seemed best. The railway surgeon was supposed to, and always should, have his instruments and appliances ready at hand, so as to be able to move with brief notice. These instruments and appliances should not be numerous, and all parties would find that, whatever the surgeon might bring, nothing would be more valuable where there are badly-

injured persons than a pair of *stretchers*. For the reasonably proper handling of the kind of patients usually found, they were absolutely necessary. There should be a pair certainly at every point where there was a surgeon, and they should accompany him in his response to a call. With two pieces of scantling $7\frac{1}{2}$ feet in length and 2 by $2\frac{1}{2}$ inches in width, rounded at the ends so as to form convenient handles, and a light piece placed across at the distance of eight or ten inches from either end, an efficient frame could be formed. From outside to outside of this frame should measure but 21 inches, which was wide enough to carry a stout man, and would pass through the guard-rail posts and door of a passenger car. By nailing over this a piece of canvas, or, if that was not available, any stout material, such as two thicknesses of ticking, we had a simple and cheap stretcher. The cloth should not be stretched very firmly, except at the ends, as a little bagging would afford much easier rest for the body. Of course, it was very crude and insufficient, but much better than none. A really good stretcher was so valuable that he had devoted some thought to the subject, and those that were being made for the service would fold together for convenience of carrying, the folding cross-bars being so constructed that they would not cut the canvas, and the legs automatically held in place whether down or up, all staples and hooks, that were always in the way, being dispensed with. The canvas was as short as would answer the purpose, and the handles extended not more than eight inches beyond it. Its width was such that it would just pass through the door of an ordinary passenger coach, a feature the value of which would be shown in the explanation of it in use.

Having, then, a patient with fracture, lying on the ground, the first thing to do was the application of support outside the clothing, for the purpose of preventing the sharp fragments from doing harm in handling. Supports might be made of any available material—pasteboard, a shingle, or a strip of board, and held in place with bandage, cords, or, in short, anything that would answer the purpose. He had thus temporarily dressed a fractured leg with a few corn-stalks, or lashed one leg securely to the other with two handkerchiefs. In case of a crushed limb the parts should be so managed as to drag as little as possible.

The next step was to *put the patient on the stretcher*. The best method he had found was to place one or more men on the *right side* of the patient, their duty being to lift the body. Two should take a position on the opposite side, to raise the legs, head, and shoulders, standing as near as practicable to the upper and lower part of the body respectively. They should be shown where to take hold and what to do "all together" *when commanded*. At the word, the men were to lift the patient directly upward just far enough to permit the surgeon to slip the stretcher, with its legs folded up, under the patient's hips *from his left side*, and slide it quickly as near under and parallel to the body as possible. The patient had thus far only been raised upward a few inches, and with a very slight lateral movement, almost without moving their feet, those that held him could lay him gently down on the canvas. To avoid contact with the ground, the man who handled the stretchers should keep the end on which the body was to be placed a little elevated. At once the other end was to be raised and the sufferer would have been made ready for removal with very little annoyance. If the body was very heavy or the assistants were few, those who lifted might take the patient by the shoulders and raise the body and hips off the ground. The stretchers being then slipped under, one man might take the legs and, by simply turning the body on the nates as a pivot, effect the desired result. In neither case had the body been jolted and dragged by raising it far from the ground, and especially had the jolt, jar, and dragging of carrying in arms by inexperienced men been avoided.

From this the sufferer should not be moved until he was to be placed on the *operating-table* or *in bed*. The method suggested for accomplishing the latter was to fold up the legs of the stretcher and carry it somewhat diagonally across the table and near to the surface, the patient's right hand being toward the pillow. In this position the patient on the stretcher was allowed to rest on the table. Those who were to lift the body were placed at the *patient's left side*, those who handled the legs at his *right side*. They were to take hold at the word of command and lift together, the body being raised so as to clear the

stretcher, which was then easily withdrawn, and, by a slight movement of those holding the body, it was placed in the desired position.

Removal from the table was effected in nearly the same way that the patient was first placed on the stretcher, and he might be laid in bed with as little discomfort as had occurred in placing him there. To do this most satisfactorily, the stretcher should be carried beside the bed, the patient's right hand being next the pillow, and the foot of the stretcher being brought diagonally across the bed. Two men on his left side now raised the body, one handled the legs, while the surgeon slid the stretcher from under him—which was usually easiest done from the foot—when by a slight movement the assistants laid the body in its place.

Sometimes it was necessary to *place patients in the cars* either before operation and perfect dressing, or very soon thereafter, and how to do it most readily and comfortably had been not a little puzzling. The baggage car was most convenient of access, as a cot could be passed through the side doors. It was, however, a rough place for a vigorous man to ride in, and did not answer well for the injured, even with the aid of a cot, except for short distances. He had also suspended a stretcher from the roof by means of ropes, which answered passably. This method was greatly improved by the use of long India-rubber bands slipped over the end of the stretcher-handles, the ropes being attached to them and the timbers above, their elasticity partially breaking the jar of the car. These bands being usually unattainable and also liable to break, rendered the plan practically useless, and, so far as the baggage car was concerned, we had left only rope suspension and the cot. The sleeping car was usually occupied, and its use was impracticable for the further reason that it was nearly impossible to get an injured man through the various passages leading into the seat or berth apartment. There was, then, nothing remaining but the passenger coach, and the problem was to take what was at hand and make out of it a bed in which a patient with crushed legs, arms, or ribs, or suffering from concussion, could be placed easily, and on which he could ride without detriment. It could be done by taking the back off of one seat. This was done by the removal of a few screws, and a screw-driver would always be found in the possession of the engineer. The backs of the seats next before and behind should be turned so as to leave the space of three seats open. The cushion of the seat from which the back had been removed should be turned upside down for one end of the proposed bed, and another placed in the same way on the cushion at the other end. We then had an open space of sufficient length and a double set of springs on which to place our support. If we now had our patient on a stretcher narrow enough to go through the car-door, he was not to be removed from it, but the whole passed between the iron posts and through the door into the car, the carriers taking hold of the cross-bars in lieu of the handles in passing through the door. Of course, the cars must be separated to secure the necessary space between. The stretcher with its contents was now to be laid down, the ends on our double cushion springs. If the handles were too long to lie between the open seats, one back could be raised so that they would project beneath it. This, it seemed to him, was not only a comfortable, but a thoroughly practicable means, provided we had stretchers sufficiently narrow. But we were very likely not to have the stretcher, and the patient was placed on a board. In that case he would try to arrange the board and patient exactly as he had described, believing that the double springs referred to would make it a more comfortable arrangement than could be brought about in a baggage car. Without removing the back of a seat, which might by some mishap be impossible, the backs of two could be raised horizontally, one seat intervening. By fastening them in this position a stretcher could be laid on them, but the whole jarring of the car would be communicated to the patient and add greatly to his discomforts.

In lieu of this, another method suggested itself, but it involved the lifting and handling of the patient—the very thing to be avoided. It was to take the cushions out of *three seats*, the backs of which were arranged as first described; lay a piece of board, a small pole, or anything that would reach across them at either end for a support; and place the three cushions side by side on these supports. With one cushion in addition the whole surface would be covered, and on this bed two persons could lie quite comfortably for even a long distance.

Of course, varying circumstances would suggest modifications of the methods proposed, but it seemed a valuable thing to know that in a dense forest a common railroad car might, in a few minutes, be made a comfortable means of conveyance for one whose life was well-nigh crushed out of him.

But the problem occasionally presented itself in another and really embarrassing form. It might be necessary to move a patient whose leg had been broken long before recovery was sufficient to permit its use in walking. We would suppose he could get about readily with crutches, but was unable to go up or down a stairway, and could not safely attempt even the steps at the front door. In that case two men should be selected, one rather tall and the other of less height, and the patient placed at the top of the steps, the injured side turned a little forward to allow the broken leg to swing clear in the further movements. The tall man having taken his place on the injured side, the patient should put his arm around his neck, and the shorter man take his place in like manner on the opposite side, both placing their arms around his waist. The tall man should step down one step when all is ready. The injured leg would swing clear, and the two men, slightly aided by a springing effort of the patient, could easily lift him sideways and plant him on his sound leg one step downward, and thus slowly and steadily, step by step, to the bottom. The same manœuvre would take him up stairs, save that in going up the short man should take the advance. This method was entirely practicable, but a strong-armed, low-back chair could be used satisfactorily. The patient being seated in it, one man was to step in front and take firm hold of one of the rungs; another was to seize the back, and both, moving together, could walk up or down stairs with great ease and safety, one of the carriers moving backward. The chair had this further advantage: When it was necessary to place the cripple in a wagon, a light, open-bodied spring being the best, he could be lifted into and out of it without leaving his seat until his arrival at the station, and, in fact, by no other means could he so readily be got into or off the car platform as by carrying him up and down the steep, long steps by the same method. Either of the methods described would answer, but the latter was no doubt most generally applicable.

Shock in Railway Injuries.—At the same meeting Dr. C. B. Higgins, of Peru, Ind., read a paper in which he confined himself to shock proper, ignoring the condition occasioned by loss of blood which so closely resembled shock in its symptoms, but which treatment demonstrated to be of an entirely different nature. Neither did he consider the remote manifestations of shock, but would leave that branch of the subject to the neurologists.

With the exception of burns and scalds, railway injuries were attended with greater fatality than wounds received in any other way. It was generally conceded by surgeons that the cause of the unusual mortality following lesions of this character was due to the fact that in a majority of the cases the shock was in intensity out of all proportion to the injury received. Most writers on this subject failed to give sufficient prominence to physical influences in considering its etiology. In Dr. Higgins's opinion, mental impressions were the chief, if not sole, elements to be considered in connection with the cause of the intense degree of shock so often observed following railway accidents.

Not long ago he had been called upon to visit a young man who had fallen in front of his engine and had his leg crushed; there was no other injury, yet he died, in less than three hours after the receipt of the hurt, of shock. He was confident that death would have resulted had there been no bodily injury. The terror induced by the contemplation of the consequences of the fall was sufficient to produce a state of mental depression from which it was impossible to recover. This young man was a perfect specimen of physical manhood—aged twenty-five, of sanguine temperament, and guilty of no excesses.

Shortly after the occurrence just reported, Dr. Higgins was summoned to see an old man of seventy-two who, while in an oblivious state of intoxication, had been run down by an engine and received a wound to all appearances as serious as the one in the case previously mentioned. In the latter case there was no evidence of shock, and the patient was so thoroughly under the influence of liquor that the leg was amputated in twenty minutes after the infliction of the wound,

without the administration of any other anæsthetic. The patient made a rapid and perfect recovery.

It was not his wish to have it understood that he had drawn his conclusions from the observation of the two cases reported, for he could cite a number, all tending in the same direction; in fact, all his experience as a surgeon led to the conviction that when a wound was inflicted without warning the attending shock was generally of little consequence. He had never witnessed an extreme degree of shock occurring in a person who had been injured while in a state of intoxication. How often did we hear the remark in reference to an intoxicated person who had survived some serious accident, "Had he been sober it would have killed him!"

Another case strengthened his position. An insane spinster, aged thirty-eight, eluded her attendants and threw herself in front of a moving train, receiving injuries which required the amputation of both legs. In her case there was no hæmorrhage and no shock. When freed from the influence of the anæsthetic, after the completion of the operation, she was found to be in possession of her right mind and had so remained ever since. She speedily recovered from the effects of the accident without the occurrence of an unfavorable symptom.

Entertaining the views he did in relation to the cause of shock, his treatment would naturally be directed toward securing a state of mind as little influenced by fright as possible. Professor John C. Dalton, in his work on "Physiology," when speaking of shock, said: "It is only after nervous irritability has been restored by repose that voluntary motion and sensation are re-established." It would be well for us in the treatment of shock, such as we met with in railway practice, to keep this statement well in the foreground and govern our efforts to secure reaction accordingly. Many patients had been thrown into a condition of more profound collapse by the too vigorous application of so-called restoratives, who, if left to themselves in seclusion and quietude, would have recovered.

It was of the first importance to remove the patient, as soon as possible, from the scene of the accident, to prevent his being surrounded by the curious crowds that were sure to congregate upon occasions of this kind. The remarks made by thoughtless and ignorant people in the hearing of the victim in reference to the serious nature of the injury added greatly to his depression and lessened his chances for recovery. He should be conveyed to a well-ventilated apartment, and only such persons admitted to the room as might be necessary to care for him properly. The surgeon and attendants should make every effort to conceal their anxiety, for the apparently lifeless patient was often possessed of sufficient vitality to comprehend his surroundings.

It would generally be found that the victim had been liberally dosed with whisky or brandy before the arrival of the surgeon. He wished here to express his unqualified approval of the position taken by the late Dr. John T. Hodgen, at the meeting of the American Medical Association in 1873, in reference to the administration of alcoholic stimulants in the treatment of shock. When the stomach was sufficiently active in these cases (which was not often) to allow of their being appropriated, they were of no use. It frequently happened that, when reaction was secured, the stomach was full of the alcohol, and the assimilative function being re-established, the stimulant was rapidly appropriated, and we soon had a condition to contend with which was as dangerous and fully as difficult to overcome as the original trouble.

The chief object in the treatment of shock was to secure repose. This was best accomplished by the hypodermic administration of morphia, and in these cases it would be found necessary to use more than the ordinary dose to obtain the desired effect. If from any cause morphia should be contraindicated, other might be administered hypodermically in drachm doses, frequently repeated. In addition to this treatment attempts should be made to restore the temperature of the body to the normal standard by the application of dry heat. These applications should be made with as little disturbance to the patient as possible. The practice so frequently resorted to of applying cloths wrung out of hot liquids of various kinds, owing to the rapid evaporation, had an effect just the opposite of that intended. The use of mustard plasters, friction, electricity, etc., he disapproved of, as the excitement attending their application overbalanced any good they might accomplish.

If we failed to secure reaction by the maintenance of absolute quiet,

the judicious administration of sedatives and the application of heat in the proper manner, we certainly should not add to our chances of success by resorting to the numerous other applications recommended by various authorities as useful in this condition.

As to the time for operation in cases of shock: If the patient showed signs by increased strength of pulse and otherwise that reaction was being established, the sooner the operation was performed the better, for the administration of the anesthetic had a decidedly beneficial influence in promoting the condition of mind which we had been directing our treatment to secure. He thought a surgeon, unless he had so firmly established his reputation as to be out of reach of adverse criticism, would be very foolish to begin an important operation upon a patient so thoroughly under the influence of shock as to be insensible to pain and oblivious to all surroundings, and, consequently, in no need of an anesthetic.

Recent Paris Theses.—According to a recent number of the "Progresses médicaux," theses had been set down for the dates named as follows: July 21st: The Treatment of the Pedicle after Abdominal Hysterectomy, by M. Amiot; The Spontaneous Cure of Cold Abscesses and Congestive Abscesses, by M. Forget; The Torsion of Arteries and Secondary Hemorrhage, by M. Charlier; Pyæmia, by M. Brou-Ducalud; Compression of the Median Nerve by a Faulty Callus of the Lower End of the Radius, by M. Leclerc; The Treatment of Simple and Complicated Hare-lip, by M. Denise; Local Temperatures and Pulmonary Phthisis, by M. Mondon; Edemas of Nervous Origin, by M. Artus. July 22d: The Indications and Contra-indications for Ignipuncture of the Cervix Uteri, by M. Gonzalez; Aortic Insufficiency consecutive to Atheroma of the Aorta, by M. Cailliet. July 23d: The Treatment of Psoriasis, by M. Bellan; *Mal Perforant* in the Pre-ataxic Stage of Tabes, by M. Delay; Rupture of the Supra-patellar Tendon, by M. Emery-Desbrousses. July 24th: The History of Tracheotomy, by M. C. Bonnet; An Historical Essay on the Calculous Affection of the Liver, from the Time of Hippocrates up to that of Fourcroy and Pujol (1801-1802), by M. Muleur; Dilatation of the Stomach following Typhoid Fever, by M. Montoya; Non-albuminous Nephritides, by M. Delespierre. July 25th: Hyper-trophic Syphilitic Chancre, by M. Zwetich; Derangements of Nutrition in the Pre-ataxic Period of Tabes, by M. Portalier; The Treatment of Trichiasis, and on Extraction by Hotz's Method, by M. Giraud; Subcutaneous Gummata, by M. Basset; Polypoid Vegetations of the Stomach, by M. Bruneau. July 26th: Fractures in Syphilitic Subjects, by M. Gelle; The Amplitude of Convergence, by Mlle. Ellaby; Ruptures of the Uterus in Labor at Term, by M. Labusquière; Pregnancy and Parturition in Young Primiparae, by M. Peyrat. July 28th: Some Accidents of Congenital Atresia of the Prepuce and their Treatment, by M. Piussan; Surgical Intervention in the Treatment and Diagnosis of Tumors of the Bladder in the two Sexes, by M. Pousson; Chronic Osteoarthritis of the Knee, by M. Salmon; Medical Hydro-pneumopericardium, by M. Armesday; Syphilis of the Tonsils, by M. Pivaudran; Paralysis in the Course of Hepatic Colic, by M. Bourdichon. July 29th: Typhoid Fever with Influenza-like Onset, by M. Millée; Adynamic Dilatation of the Stomach, by M. Enrique de Argeaz; Insanity following Sunstroke, by M. Douy; The Development of the Wolfian Body and the Kidney in Vertebrates, by M. Baron; The Development of the Liver, by M. Vauthier; Blennorrhagic Erythemas, by M. Mesnet; Blennorrhagia as a Parasitic Affection, and its Treatment by Injections of Bichloride of Mercury, by M. Chameron; The Gastric *Bruit de Clopote-ment*, by M. Baradat. July 30th: The Electrical Treatment of Fibrous Tumors of the Uterus according to Dr. Apostoli's Method, by M. Carlet; Phlegmons and Deep Abscesses of the Temporal Region, by M. Pouillande; Exostoses of the Subscapular Fossa, by M. Mesnard; Deep Varices of the Lower Limb, their Signs and the Accidents to which they may give rise, by M. A. Gautier; The Treatment of certain Diseases of the Eyes by Igneous Cauterization, by M. Letellier; The Treatment of Exophthalmic Goitre with Iodine and its Compounds, by M. Galup; Lymphadenoma of the Bones from a Clinical Point of View, by M. Périer; Spasmodic Jaundice, by M. Mendiboure; Chorea Gravidarum, by M. Gayraud. July 31st: The Discovery of the Bacillus of Tuberculosis in other Products than the Expectoration, by M. Aguet; Tropic Troubles in General Paralysis, by M. Ramadier; The Course and Dura-

tion of Locomotor Ataxia, by M. Lucas; The Functional Independence of the two Cerebral Hemispheres, by M. Berillon; Dislocations of the Humerus complicated with Fracture of the Upper Part of the Bone, by M. Oger; Fatty Matters in the Urine, with a Bibliography of the Entozoa of Chyluria, by M. Monvenoux; The Hypnotic and Sedative Action of Paraldehyde in the Different Forms of Insanity, by M. Nercam; Phlegmasia Alba Dolens in Typhoid Fever, by M. Cazauiellin; The History of the Protection of Childhood in Rome, by M. Moutier. August 1st: Embryotomy as regards the Sufferings it causes the Fetus, and the Means of avoiding them, by M. Kh'ntiriann; Filamentous Insertion of the Cord, by M. Bessière; Pregnancy and Labor in Old Primiparae, by M. Courtade; The Complications of Cancer of the Uterus, by M. Caron; Experimental Progress in the Study of the Functions of the Brain, by M. Levillain; The Surgical Treatment of Obstinate Neuralgia of the Inferior Dental Nerve of Peripheral Origin, by M. Ricoux; Lithiathy in Children, by M. Ducasse; Blennorrhagic Cystitis, by M. Leprevost; The Surgical Treatment of Purulent Pleurisy in Children, by M. Branthomme; The Action of Digitalis in Diseases of the Heart, by M. Fleurot; Reflex Neuralgias of Dental Origin, by M. Ferrier. August 2d: Hydatid Cysts of the Base of the Skull, by M. Odile; Gangrene of the Limbs in the Course of Chronic Nephritis, by M. Grouillard; Cancer of the Pleura, by M. Vinet; Aseptic Catheterization in Lying-in Hospitals, by M. Prieur; The Infantile Pelvis considered in regard to its Form and the Relation between the Diameters of the Superior Strait, by M. Turquet; Puerperal Paralysis of Eclamptic Origin, by M. Bernard; The Mechanism of Death by Intense Electrical Currents, by M. Grange; The Use of Chloroform in Tracheotomy, by M. Soyer.

The Inebriates' Home at Fort Hamilton.—According to the sixteenth annual report of the president of this institution, just issued, there was one patient fewer treated in 1883 than during the previous year. The period of treatment for each individual was about the same, or about four months. With the present capacity of the building, which has been filled to overflowing the greater part of the year, it was impossible to treat a larger number of individuals, and it has therefore been necessary to refuse many worthy applicants for admission, owing to the want of adequate accommodations. This condition demonstrates the fact that the institution has been and is of great value, and that its benefits are desired by a larger number of people than can be cared for.

Since the construction of the building there has been no enlargement or increase in its capacity, and, although when it was built it appeared to be ample, the necessity now seems urgent that some way or means should be devised whereby its capacity may be materially increased, or its usefulness will be considerably restricted. There is still constant demand for accommodations for females belonging to the better class, for which there is absolutely no room; and within the president's knowledge there is no place either in this State or in the United States where such persons can be properly and judiciously treated.

From these facts it would appear that the institution is an absolute necessity, and that without it a numerous class would be forced into the penal institutions, although not deserving of punishment but yet in need of some restraint, to their great detriment, and at an increased cost to the community.

Mellin's Food for Infants and Invalids.—A recent analysis by Mr. G. W. Wigner, the President of the Society of Public Analysts of England, throws considerable light, not only on the composition, but on the physiological action of this popular preparation. It appears that it contains nearly 87 per cent. of dextrin, maltose, etc., soluble in cold water.

As Mr. Wigner points out, it is not a mere starch or sugar food, but a soluble preparation, containing those nitrogenous and phosphatic principles which contribute largely to the growth of bone and tissue in young children. Being thoroughly malted, it is not only readily digestible itself, but actually assists in the digestion of milk and other foods with which it is mixed. It must of necessity be of great value in the case of feeble infants who can not digest ordinary starchy foods. Mr. Wigner's analysis has evidently been performed with great care, and is of much interest."—*British Medical Journal*, May 3, 1884.

Lectures and Addresses.

ON THE DEVELOPMENT OF PHYSIOLOGICAL CHEMISTRY AND ITS SIGNIFICANCE FOR MEDICINE:

AN ADDRESS DELIVERED AT THE CELEBRATION OF THE
OPENING OF THE NEW INSTITUTE FOR PHYSIO-
LOGICAL CHEMISTRY OF THE IMPERIAL
UNIVERSITY OF STRASSBURG,
FEBRUARY 18, 1884.

By PROFESSOR FELIX HOPPE-SEYLER.

Translated by T. WESLEY MILLS, M. A., M. D.,

DEMONSTRATOR OF PHYSIOLOGY, MCGILL UNIVERSITY, MONTREAL, CANADA.

(Continued from page 171.)

In the most recent times different hypotheses bearing on the chemical structure and peculiarities of living protoplasms have been published; they do not, however, taken together, agree with the known facts. Their mechanical and chemical behavior, so far as they have as yet been investigated, force us to the supposition that *one and the same protoplasm, according to the influences which from without are brought to bear upon it, may form [darstellen] two entirely different bodies*—different in chemical structure and in action on other organic substances which come into relation with the same, and also in attraction for water.

The protoplasms further effect chemical changes through which, on the one hand, fermentative decompositions, and, on the other, anhydrides, are formed. Both processes stand in such decided opposition to each other that they can not proceed at the same time from one and the same substance. In the plants and animals of higher organization we can ascribe to one cell the one function, and to another the other. In the lowest unicellular organisms this is not possible: in these, both processes must go on in the same protoplasm; they form albuminous substances, fats, glycogen, or cellulose, and such like, and also break up these substances.

It would appear that it is observation of just these lowest, simplest forms of life that enables us to form the clearest conceptions.

Beer yeast-cells in a saccharine fluid change grape-sugar into alcohol and carbon dioxide in the complete absence of free oxygen, and can continue these processes for months without either growing or multiplying themselves, when, indeed, the food-supply is abundantly present and the temperature favorable. According to certain observers, the yeast-cells do grow and multiply, but *there is no doubt that it must be admitted that growth and multiplication are insignificant.*

A portion of the same yeast-cells, brought into a saccharine fluid in the presence of oxygen, forms little or no alcohol, separates some carbon dioxide, with absorption of oxygen, grows, and, moreover, multiplies abundantly under similar conditions of temperature and nourishment.

The bacteria of decomposition [*Fäulnisbacterien*], brought into watery extracts of flesh in the presence of oxygen, decompose albuminous matters, creatin, sugar, and lac-

tic acid into leucin, hydroparacumarsic acid, indol, skatol, ammonia, carbon dioxide, hydrogen, and sulphured hydrogen.

They are motionless and do not multiply; however, the latter is denied by some observers.

The same bacteria, under precisely similar conditions but with oxygen present, form no hydrogen, no organic decomposition products; only carbon dioxide, water, and ammonia; *they multiply abundantly and are in lively motion.*

The formation of anhydrides, to be recognized in the growth of organisms and their multiplication, happens either only, in the main, in the presence of oxygen, or, at least, much more abundantly than without it. However, oxygen can neither of itself form anhydrides nor be the sole cause of the movements of the bacteria.

Though oxygen is of itself powerless to act as an oxidizer in such cases, yet, in the presence of nascent hydrogen, it does possess such power; and this latter is always the case in putrefactive processes. There is an opinion, as yet very widely diffused, that these lower organisms comport themselves throughout otherwise than the higher plants and animals. Differences not a few are to be observed, but, just as these lower organisms contain the same substances in their protoplasm as the highest (globulin substance, lecithin, cholesterin, nuclein, and potassium) so do they in their chemical processes show a remarkable agreement in the fundamental types. If we suppose (and there is no fact opposing it) that also in the highest organisms indifferent oxygen in the same manner as in the lowest succeeds in oxidizing, so might the general protoplasmic phenomena in plants and animals be thus formulated:

Distinction must be made between (1) the protoplasm incapable of stimulation, as it continues to be in the absence of oxygen, acting with a ferment-like decomposing power on albuminous matters and many other substances, and (2) the protoplasm capable of stimulation, of less density than the first, of greater capacity for attracting water and not inciting fermentation. In the presence of water the second is changed into the first, through addition of the elements of water in chemical combination, in consequence of the weaker or stronger shocks of the so-called stimulation, through different modes of motion—electrical, thermal, chemical, or mechanical motion. The first protoplasm is again changed into the second BY THE PRESENCE OF OXYGEN, since, by the decomposing action of the first protoplasm, oxygen is rendered active, and through the active oxygen the second anhydriated protoplasm arises. If, under such circumstances, substances present themselves which can be easily anhydriated, they pass over into anhydrides. The anhydride formation happens, accordingly, through the reformation of anhydride protoplasm in consequence of the influence of active oxygen on the protoplasm with ferment-like action.

It would lead too far into details to demonstrate the agreement of these hypotheses with all the results of observation on them *in the entire realm of the organic world which they include.* Let it suffice to choose from very different classes of organisms individual representatives, and demonstrate their agreement.

What I have already said of beer yeast-cells and bacteria is in unison with the hypotheses, so I will not repeat.

The muscles of men and vertebrates, through stimulation, change in density, break up glycogen, and form lactic acid; the latter is, however, in the presence of oxygen, oxidized; carbon dioxide and water are formed in the proportion the carbohydrates furnish, and in correspondence with the strength and duration of the stimulation. The change into the stimulated condition follows also in the absence of oxygen. The removal of oxygen calls into existence lasting tetanus (poisoning by hydrocyanic acid, rapid death by bleeding, hanging, etc.). On the other hand, under normal presence of oxygen, in order to maintain a stimulated condition in some measure lasting, continuous repetition of the stimulus is necessary, since the active oxygen at once forms the anhydrated protoplasm.

In glands, in consequence of stimulation, a secretion of a watery fluid follows, which can have only chemical, not physical, causes, in that it is independent of the blood-pressure, and the fluid secreted does not contain those salts which, in all the transudations, pass over from the blood in definite proportions.

With this secretion abundant formation of carbon dioxide and of warmth takes place at the same time. Very clearly were these conditions observed in the secretions of the insect-eating plants, as so admirably described by Charles Darwin.

Mechanical phenomena of motion [*Bewegungserscheinungen*] in plants, especially the remarkable movements of the petioles of *Mimosa pudica*, are of the same nature as the secretion of water from protoplasm, in consequence of the stimulation already mentioned. That the vacuole formation in numerous protoplasts, also in the *Amœba* itself, arises from a similar secretion of watery solution from the protoplasm in consequence of stimulation, is highly probable. The mechanical movements of *Amœba*, etc., toward the point of stimulation is explicable only through these hypotheses.

Numerous and very different in kind are the observations on higher, especially warm-blooded animals, which have afforded the demonstration that with the prevention of the access of oxygen to the organs the stimulative capacity sinks, while, in consequence of this hindrance, the extent of the decomposition of tissue and of chemical interchange rises.

When a stream of blood containing oxygen is conducted through the living kidneys, the union of glycocholl and benzoic acid which takes place has been shown to be an anhydrating process. The opposite process, however—viz.: the splitting up of hippuric acid and similar compounds under addition of water in the living organs—is observed.

Presumably the last process takes place also without the presence of oxygen, and can be effected in the protoplasm incapable of stimulation.

Let these intimations suffice to indicate how in one realm of physiological chemistry—and that the largest—results unite to induce further investigation of problems becoming ever more comprehensive; and how, further, all living beings, of form and life-phenomena the most widely

different, appear to owe their fundamental structure to an original chemical organization, with properties common to them all.

In the preface to his "Animal Chemistry," Liebig, in 1842, said: "The new chemistry has, with all its discoveries, furnished only insignificant service to physiology and pathology, and no one can deceive himself as to the causes of this failure who takes into consideration that all the methods introduced into the realm of inorganic chemistry, the knowledge of the behavior of the simple bodies, and the compounds that might be made in the laboratory, could be brought into no sort of relation with the living animal body and the character of its components." Since that time this has been changed; but it would be vain to reckon on a further advance in physiology from the side of the chemist when the questions of biology lie so very far away from him—questions whose answers bring for the theoretical chemist but very little profit. While theoretical chemistry and chemical technique are closely linked with one another—while the one derives great advantage from the other—the relation to physiology and to the whole of medicine is entirely different. But even the technique has found it necessary to take the solution of certain problems in hand, with what good or ill luck might follow.

For the chemical manufacture of dye-stuffs, for the sugar industry, for beer and brandy manufacture, there now exist special, and in part excellently directed, laboratories, in which for special objects these branches are practiced and partially taught. In all civilized countries there are now laboratories for the objects of agriculture. Physiological and pathological chemical laboratories have also been established, but, with very few exceptions, they have restricted means and no independence. The importance of chemistry for the development of physiology and pathology did not escape Virchow's sharp ken. He established in 1856 the first better-endowed and tolerably independent laboratory in his new pathological institute in Berlin. In Munich, through Liebig's influence, a series of diligent researches was made on food and nutrition [*Ernährung und Stoffwechsel*]. In Tübingen the laboratory for applied chemistry was restricted almost exclusively to the subject of medical chemistry. Several of the ablest physiologists, such as Brücke and Pfleger, applied themselves with lively interest to the solution of the problems of physiological chemistry, and encouraged and advanced this science.

In the Physiological Institute of the Berlin University, opened a few years ago, there is a suitable laboratory for physiological chemistry, which has already done good service alike to teaching and to science.

Though, after the example of Frerichs, several clinicians fostered physiological and pathological chemical investigation, yet in most German universities the chemistry of physiology has not received the consideration and advancement it deserves.

It can be said in praise of the physicians of all times, and not in small numbers of those of the last ten years, that they, with much attention for the objects of the diagnosis and treatment of disease, sought to apply what science and the technique supplied. Astonishing must it be

then, that the great majority of the physicians in the most recent times felt coldly enough over the advance of chemistry in general—much more so than was the case at an earlier period, and that within my recollection—while a small minority kept their eyes fixed on it with great interest.

One or another will perhaps say that these advances may be of really great significance for the science of medicine, but of little applicability to the practice of medicine. With regard to numerous results of the anatomical and physico-physiological investigations, and such as have been spoken of above by myself, bearing on the chemical behavior of living cells in general, it is not to be expected that they should have a direct bearing on practice. But quite different is it with very many results of the most recent investigations of physiological chemistry. So can I not understand how at the present day a physician can recognize, follow in their course, and suitably treat, diseases of the stomach and alimentary canal, of the blood formation and decomposition, of the liver, kidneys, and urinary passages, and the different forms of poisoning—how he can suitably regulate the diet in these and in constitutional diseases—without the knowledge of the methods of physiological chemistry and of its decisions on questions offering themselves for solution, and without practical training in their application.

Is it possible we must conclude that there is an overburdening of the medical student while following out the curriculum, and that this is the cause of the insufficient attention in general paid to the chemical problems of medicine?

I am far from denying an overburdening; it exists, in fact, in high degree, and the lengthening of the term of study (one semester) now in force does not suffice to obviate it. This overburdening, however, is not the only cause, nor is it distributed uniformly over the different departments of study.

The principal cause of this unsymmetrical distribution lies in the form which the medical curriculum has taken in the last ten years. The really valuable results in the great field of normal and pathological investigation which have been achieved through the improved microscopes of the last four decades; the triumphant victory won by the microscope for pathology in the direction of pathological anatomy over the earlier prevailing but insufficiently grounded philosophical physiology; the insight into the significance of the lowest fungi, also achieved through the microscope—have in medicine lent to the anatomical method of demonstration and investigation undue weight, which, at first useful in explanation of obscurities, became gradually more and more pressing, even crushing, on the remaining branches of the medical curriculum.

The skeptical fanaticism of the injudicious champions of the Vienna school, which sought to rob the physician of all belief in tradition, has also in its after-working exerted a paralyzing influence on chemical and therapeutical efforts. Amid this sea of doubts the anatomical facts appeared to be the only thing that remained firm. On this was joined the transformed but very meager pathology. For inde-

pendent clinicians this state of things could not suffice; the sterility ensuing through this sovereignty of morphology could not remain hidden from the penetrating. Many clung with lively interest to the means which the researches on nutrition [*Stoffwechsel*] furnished for the solution of clinical problems. But insight into the hidden springs and processes of life remained veiled. That they are chemical processes we know right well, but their solution requires the most painstaking work. We trust well to the certain fundamentals of chemical investigation; but only slowly, and contending against the most diverse hindrances, can we penetrate into the fine machinery which in healthy and in diseased beings determines life [*das Leben ausmacht*]. On other than chemical paths do we not advance. Who will deny that?

We should not object that pathological investigation and not the physician's practice has to do with this. Every observing physician must admit that in this relation there exists no difference.

The commercial physician [*der ärztliche Geschäftsmann*] alone can content himself with mere patterns; for the true physician every genuine case does and must furnish a special study.

A short time ago one of the most active clinicians,* Leube, raised a warning voice against the underestimation of chemistry for medicine. *That to it the future of the science of medicine belongs can with certainty be discerned.*

After what has been said, there remains no doubt as to the aims which the erection of this spacious new structure leads us to strive to achieve. It shall be a place for the practice and study of physiological chemistry in every direction bearing on medical science. The great value which in recent times, certainly rightly, is attributed to hygiene and the very numerous necessary relations which this realm of investigation and teaching have in common with physiological chemistry, cause it the more fitly to appear that, for its practical study, space and arrangement should be made in this institute, as in great part the subjects not wholly microscopic or technical belong also to physiological chemistry, and so can never be better managed than in an institute set apart for the latter science. To avoid collision in instruction, separate rooms for work in physiological chemistry and in hygiene are provided.

Easy Liquefaction of Oxygen.—It will be remembered that Messrs. Wroblewski and Olszewski some time ago succeeded in liquefying oxygen by the use of ethylene. M. Cailletet has searched for and found a body having a still lower boiling point than ethylene, and by means of which oxygen can be very readily liquefied. This substance is simply formene or marsh-gas, which, under slight pressure and cooled in ethylene, boiling under the ordinary atmospheric pressure, is resolved into an extremely mobile, colorless liquid, which, in passing again into a gaseous state, causes such a lowering of temperature that oxygen in its neighborhood is immediately liquefied.—*Lancet*.

An Italian Society of Dermatology and Syphilography will be formed, according to the "*Gazzetta degli Ospitali*," at a meeting to be held at Turin on the 10th, 11th, and 12th of September.

Original Communications.

THE EFFECTS OF SEA AIR

UPON

DISEASES OF THE RESPIRATORY ORGANS,

INCLUDING A STUDY OF THE INFLUENCE UPON HEALTH
OF CHANGES IN THE ATMOSPHERIC PRESSURE.*

By BOARDMAN REED, M. D.,

ATLANTIC CITY, N. J.

WHAT are the peculiar properties of sea air, and in what respect does it differ from the atmosphere upon mountains and in other localities away from the sea? These are questions which it is very necessary to have clearly answered before any intelligent decision can be reached as to the probable result in any given case of an ocean voyage or a sojourn at the sea-side. The answer to them involves a study of a purely scientific character, yet one of the utmost practical importance to physicians.

Ozone, or oxygen in an active electrical state, is an important ingredient of the atmosphere at the sea-shore as well as in mountain districts, while it is nearly absent from the devitalized air of large cities. This is the most powerful oxidizing agent known, and its presence unquestionably greatly enhances the vigor and activity of all the vital processes. But both the medical profession and the general public have been made familiar with the value of ozone, to which almost magical virtues have been ascribed.

Another noteworthy property of sea air, which is less generally understood and appreciated, is its greater density as compared with the atmosphere of most inland places which have a considerable altitude. This increase of density produces numerous effects upon the human body. It enables more oxygen to be taken into the lungs with each inspiration, and thus increases oxidation. The atmospheric pressure at the sea level has been computed to be about fifteen pounds to the square inch, which amounts to from fourteen to sixteen tons upon the whole surface of the human body. At an elevation of three and four tenths miles this pressure is only one half as much. At even a few hundred feet above the sea the pressure is materially less. Now, the change from a high or even medium altitude to the sea-side involves, as one of the most direct and positive effects, an increase of the pressure upon every square inch of the body. To this fact is largely due the extraordinary feeling of buoyancy and vigor as well as the stimulation of all the nutritive processes which are experienced upon going to the shore. *Per contra*, it is a well-known fact that the effect of the lessened pressure in very high altitudes is distressing to human and animal organisms, and finally destructive to them, as has been demonstrated by aeronauts and travelers who have explored the higher mountains. Vertigo, headache, rapid pulse, and loss of appetite are among the earlier symptoms which, as the experimenter goes still higher, are intensified until finally hemorrhages from under the nails, the eyelids, and other parts, together with severe dyspnea, show the increasing peril to life.

The congestion which may be produced in a part by a marked lessening of the atmospheric pressure upon it is best shown by applications of dry cups or of the mechanical contrivance known as Junod's boot.

A person, upon being conveyed rapidly, as by rail or balloon, to a very high elevation, experiences a somewhat similar congestion of the entire exterior of the body, including the respiratory passages, which, even to their ultimate ramifications in the alveoli of the lungs, are to be considered as exterior parts, so far as regards their relation to changes in the atmospheric pressure. In other words, the interior of the lungs, being in direct communication with the air, is affected by changes in its density coincidentally with the surface of the body. Hence the frequency of hæmoptysis, as well as other hæmorrhages, and the danger to consumptives in very high altitudes. This danger is greatest, of course, during the first few hours or days after being conveyed to such a region, before the pressures upon the exterior and within the interior of the body can become equalized. In passing from the higher to lower levels, and especially to the lowest, which is at the shore, these conditions are exactly reversed. The atmospheric pressure being then increased upon the surface and within the lungs, to which the air has direct access, there is an efflux of blood from these parts to the truly internal organs of the body, such as the brain, stomach, liver, intestines, and kidneys.

This moderately augmented blood-supply increases the functional activity of all such parts, while the external organs, as the skin and the whole respiratory tract, which receive a somewhat diminished blood-supply, find abundant compensation in the directly stimulating effect of the denser air. There being besides a greater proportion of oxygen in its most energetic form, the process of oxidation is rendered more active. It follows, then, that all changes of climate involving decided changes of altitude disturb at first the balance of the circulation.

Changes from a low to a higher level tend to cause a temporary congestion of the respiratory tract and external parts, while the contrary change, such as that to the shore, in so far as the altered atmospheric pressure is concerned, tends to lessen congestion or inflammation in the bronchial tubes or lungs, but may produce a temporary plethora of the interior organs.

A very interesting study of the results of an atmospheric pressure artificially increased, as in coffer-dams, to three or four times the normal, has been made by Dr. Andrew H. Smith, of New York. He found that numerous alarming and sometimes fatal symptoms were developed in persons exposed for several hours to such enormous pressures but only after they had returned to the ordinary air.

Another result of the greater density of the atmosphere at the sea level is that it has an augmented capacity for absorbing and retaining the heat of the sun. The temperature has been found to fall one degree for every four hundred feet of altitude. Besides, a radiation of heat is constantly taking place from such a large body of salt water as the ocean, which is warmer in winter and cooler in summer than the surface of the land adjacent. Hence the air over the sea or at the shore is usually warmer in winter,

* Read before the American Climatological Association, May 3, 1884.

though, for the reason just stated, cooler in summer than that of interior places in the same latitude.

Another peculiarity of a strong sea air, such as is breathed on ship-board, and at the shore during a sea breeze, is that it is always moister than the atmosphere of inland places, and more or less impregnated with saline particles.

Much is said about the relative humidity of various sea-side places, but it may be accepted as an axiomatic fact that air blown directly off the sea anywhere is much moister at the water's edge than the air farther inland.

Sea-side towns located at the extremities of capes, where the wind blows off large bodies of water on nearly all sides, will, of course, have a more humid air than those not so exposed. Thus Atlantic City has been found experimentally to have a much drier air than most sea-shore resorts. This may be partly due to the trend of the coast at that point, and to its distance from the mouth of any large river, since winds often seem to focus at the mouths of rivers, and the stronger the winds from the seaward the greater the degree of moisture. Furthermore, the large extent of very dry, sandy barrens directly behind the town causes the land breezes, which always prevail during a part of the time at every point upon the coast, to be particularly devoid of moisture. Let it be understood, then, that sea air, whether at the tropics or at the extreme north, is always a distinctly moist air, and, notwithstanding the prevalent assumptions about the value of dry air in the treatment of nearly every disease, there is no doubt that to the greater humidity of sea air are partly due some of the peculiar advantages which clinical experience has shown to result from a residence at the sea-shore.

It is a wet soil rather than a moist air which is so injurious to health, and a considerable portion of our Atlantic coast, including that bordering the southern part of New Jersey, has an exceedingly dry, porous, sandy soil, which permits water to rapidly sink away, except during spells of very rainy weather.

The mucous membranes of the respiratory tract, then, are, during an ocean voyage constantly, and at the sea-shore intermittently, bathed with an alkaline and alterative spray, which, in case of the sojourner at the sea-side, can be made strong or mild accordingly as he spends most of his time at the water's edge or some hundreds of feet farther back.

Still another important consideration is that sea air—i. e., air blown directly off the ocean—is pure in the sense of being free from all noxious effluvia, and especially from the bacteria which are now believed to cause so many formidable diseases.

Thus, to briefly summarize, it has been shown that sea air contains more ozone, is denser and therefore more invigorating, as well as moister and purer, than the atmosphere of interior localities; that it is also warmer in winter and cooler in summer; and, besides, that it contains in suspension a very appreciable amount of saline particles, which are alkaline in reaction, and possessed of alterative virtues. It has been shown, further, that the greater atmospheric pressure at the sea level exerts certain effects upon the local blood-supply of various organs of the body.

These facts being admitted as well established, the

therapist should, on *a priori* grounds, expect certain definite effects from sea air upon patients afflicted with diseases of the respiratory organs. We might expect (1) in all suitable cases a general tonic influence, with increased appetite and improved assimilation; (2) we should look for a direct and positive stimulant and alterative impression (sometimes, doubtless, too strongly stimulant) upon the mucous membranes of the upper air-passages, with, probably, the same effects in a less degree upon the bronchial tubes and alveoli.

A large number of invalids, suffering with the various affections of the respiratory tract, have been seen by me at Atlantic City. Chronic nasal catarrh is often temporarily benefited at that place, particularly in summer, when sea-bathing can be indulged in. The effects of a residence there during winter, as well as summer, have occasionally produced considerable amelioration of that stubborn malady through the improvement in the general nutrition. But, so far as my experience goes, no actual cures of the disease have occurred without the help of local treatment.

Chronic laryngitis is not uniformly improved by sea air, though it is frequently benefited by a prolonged stay at the shore, and is occasionally cured there with very little treatment.

Volumes could be filled with the testimony of authors as to the value of sea air in chronic bronchial affections. Some make a distinction in this regard between dry and moist bronchitis, maintaining that persons with the former may expect most benefit. This does not accord with my observations. I have found all forms of chronic bronchitis, except those associated with advanced cardiac disease, improve at the shore, as a rule, though there have been exceptions. In numerous cases persons, who at home regularly suffer from winter coughs, have escaped almost entirely at the locality mentioned.

Hay fever is more of a neurosis than an actual lesion of any respiratory organ; but it will be in order here to note that sea air, as exemplified at Atlantic City, often proves remarkably curative in this affection.

In spasmodic asthma the results of sea air might be expected to vary with the degree of irritability of the respiratory centers and bronchial membranes. Clinical experience, in like manner, shows variable results. Many subjects of spasmodic asthma have entire immunity at the same sea-shore resort, while other cases of apparently like character are aggravated. As has long been observed with this singular affection, there seem to be no means of determining in advance what the effects of any particular climate will be upon any individual case.

In vesicular emphysema there has been observed at the shore, as would be expected, a marked palliation in consequence of the greater density of the air and its increased proportion of oxygen.

Dr. Bartholow says: "Of all the means hitherto proposed for the relief of emphysema, nothing has approached compressed air in effectiveness. Indeed, this is the only scientific remedy which has as yet been brought forward for the treatment of emphysema. . . . The object of compressed air is to relieve the breathing by supplying more oxygen,

and it effects an equalization of the blood in the two systems by redistributing the pressure. By retarding the breathing and the actions of the heart, the contractions are firmer and the cavities are better emptied. The improved condition of the blood, the result of a better supply of oxygen and increased excretion of carbonic acid, induces a better state of digestion and assimilation. By breathing compressed air the pressure is transferred from the venous to the arterial system, and, while the amount of blood on the right side is diminished, on the left it is increased."*

Pre-eminently important among the diseases of the respiratory tract are those several lesions which are conveniently grouped under the popular term consumption. These include chronic catarrhal pneumonia or caseous phthisis, fibroid phthisis, and tubercular phthisis. I have noted the progress at Atlantic City of numerous cases of each of these forms of lung disease. My observations have led me to the conclusion that, as a rule, consumptives in the early stages, before softening has begun, do well at the sea-shore, at least in that locality. The great majority of such patients have progressed favorably during their stay there. Quite a number of persons having a portion of one lung consolidated have become permanent residents of the place on account of the marked improvement in all their phthisical symptoms produced by the climate. In a considerable proportion of the cases which have continued under observation, the diseased process seems to have been arrested. On the other hand, where there has been much irritative fever with profuse night sweats at the time of their going to the shore, the patients have not done so well.

This has been no doubt largely due to the fact that such invalids usually insist upon walking or being carried out daily, even when the most feverish. They and their friends have nearly always gone to the shore strongly impressed with the idea that they must spend as much of their time as possible in the open air, and especially upon the beach within the influence of the salt spray, whereas such acute exacerbations as just referred to demand, above all else, perfect rest, soothing treatment, and a not too stimulating air. Furthermore, the friends of the consumptive are apt to believe that, next to walking or driving a large part of every day upon the beach, the one thing needful is to force as much strong food into the stomach as it can possibly retain, whereas during the continuance of hectic fever in phthisis, as in other febrile conditions, a carefully selected diet, not exceeding either in quality or in quantity what can be easily digested and assimilated, is absolutely indispensable to a cure, or even improvement. When such patients have been willing to submit to a rational treatment at the shore, including rest in bed during the periods of excited circulation, the febrile symptoms have often been controlled, and then, during the quiescent period ensuing, exercise in the open air with judicious feeding and a generally stimulating treatment has proved serviceable.

A few exceptional cases of phthisis which had advanced to the formation of cavities have been observed to pursue a favorable course at Atlantic City. These have been of a

slow, chronic type, and the patients have been under persevering treatment, including usually a somewhat active counter-irritation over the diseased portion of the lung. They have been persons possessed of strong hearts and good stomachs, capable of tolerating cod-liver oil and the hypophosphites.

Under less favorable conditions, however, consumptives in whose lungs cavities have formed go down rapidly there as elsewhere. One case may illustrate the different progress at the shore of phthisis in its early and late stages: A young lady of eighteen went from New York to Atlantic City in the spring of 1882. Dr. Loomis had seen her in consultation, and diagnosed consolidation at one apex. She improved remarkably during a sojourn of a month or more, gaining in flesh and strength and almost losing her cough entirely. She spent the summer in some mountain region and returned to New York in the fall. The following March she went to Atlantic City in a deplorable condition. She had a cavity at one apex, and a recent patch of infiltration at the other. There was profuse purulent expectoration, with high fever, which had been much aggravated by even the short journey from New York. Besides, the stomach had broken down and there were indications of tubercular deposit in the bowels. She sank rapidly, and died within three weeks.

My observations in this regard are in the main confirmatory of the statements of the leading modern authorities on climate in the treatment of phthisis. Nearly every recent author of any note who has made a study of the subject bears testimony to the value of sea air in pulmonary disease when resorted to in time. Dr. Madden, in his "Health Resorts of Europe and Africa," says: "With few exceptions, the localities resorted to in winter by consumptive patients are situated on the sea; and certainly this predilection is well founded, for such situations are more equable in temperature, being cooler in summer and warmer in winter, and less subject to sudden transitions or great extremes of temperature than inland places. As a general rule, therefore, I would select a locality on the sea-shore for the residence of consumptive patients."*

Professor John Hughes Bennett, † in Reynolds's "System of Medicine," recommends numerous climates as particularly suited to consumptives, all of them being either sea-coast regions or islands in the sea.

Dr. John Parkin, ‡ in his work on "Climate and Phthisis," condemns most of the southern resorts prescribed by writers, and maintains that cold climates rather than warm ones are the best for phthisis, yet has a kind word to say in favor of several of the English sea-coast towns as offering a prospect of benefit to consumptives during certain times of the year.

Tanner,* in his "Practice of Medicine," first cautions

against a change of climate after the beginning of softening or the formation of cavities, and then proceeds to recommend as desirable residences for consumptives a long list of sea-side places.

To go further back, the illustrious Laennec,* the father of auscultation, himself bore emphatic testimony to the usefulness of sea air in phthisis.

Dr. B. W. Richardson, in his "Preventive Medicine," says: "The influence of a seafaring life as a preventive of phthisis has been a matter of important observation. In 1856, Boudin showed that while the deaths from consumption in the British army were, in the Line, 8.9 in 1,000 men, and in the Guards 12.5 in 1,000 men, in the British navy, 1830 to 1856, inclusive, the deaths from phthisis were 1.76 in 1,000 men."†

These citations might be almost indefinitely extended, but the foregoing are enough. The accumulated experience of all the centuries back to the time of Hippocrates points to the conclusion that sea air is, in some measure, a prophylactic against pulmonary phthisis; that it may prevent the development of incipient cases under favorable conditions, and that it often proves beneficial in the disease even when fully established, though not usually advantageous after softening begins.

A CASE OF EPITHELIOMA OF THE ANO-RECTAL REGION,

WITH REMARKS.‡

By CHARLES R. CRANDALL, M. D.,
PORTLAND, MAINE.

Mrs. W., aged thirty-four, married, was the mother of two children, aged, respectively, seven and ten years. Her family history was good in every respect; her mother died of "asthma" (†) at the age of sixty-six; her father is still living at the age of seventy-seven. She never lost any brothers or sisters. Always had good health until she began to bear children. At the time of her last confinement, seven years ago, she had a tedious getting up, and has never enjoyed perfect health since.

In January of 1883 she had an attack of acute ovaritis, characterized during the onset by repeated chills, fever, vomiting, rapid pulse, swelling and pain in the region of the left ovary, and prostration. With this attack she was sick about two weeks, convalesced slowly, and never seemed to regain the degree of health which she had previously enjoyed.

Early in the summer she went into the country, where she remained nearly three months. Upon her return she reported for treatment, but sadly changed in general appearance. Her complexion was pale and sallow, and she had lost about twenty pounds of flesh. About the time she went into the country she began to suffer from indigestion, then became unusually constipated, piles developed which caused her great pain day and night, and her general strength became impaired.

Upon inspecting the anus I found three large, hard, painful external hemorrhoids which were entirely covered with integument. I instituted treatment as was indicated and urged the

importance of due preparation, and, as soon as possible, an operation upon the anus. Later on it was noticed that the hemorrhoids were not influenced by ordinary treatment, defecation was difficult and painful, bleeding occurred at each stool, and the inside surfaces were apparently ulcerated. Owing to the excessive tenderness of the parts, thorough rectal examination was not successfully carried out. Delays ensued until it was decided that she should submit to an operation on the 3d of December, 1883.

With the assistance of Dr. Gordon, surgeon to the Maine General Hospital, and Dr. B. B. Foster, the patient was etherized and was placed in the lithotomy position. Thorough examination of the rectum revealed the presence of incipient epithelioma of the ano-rectal region, extending upward nearly two inches. To the touch the sensation was abnormal, but much unlike the hard, tough, infiltrated structure so often met with in malignant growths of the rectum. The lower portion of the rectum appeared dilated, and the mucous surface was irregular, roughened, vascular, and somewhat ulcerated. It would be nearly correct to state that the tissues were soft and movable, but that at points there was a moderate degree of thickening. It appeared as if the growth had developed in papillary eminences and irregular patches, of variable size and thickness, upon the mucous membrane, and these were more or less scattered all around the ano-rectal surfaces, but, perhaps, were largest and most numerous upon the vaginal side. The patches were slightly elevated, some of them abraded and highly vascular, doubtless causing the pain and bleeding she had experienced during defecation. As yet there did not seem to be any invasion of the deeper structures.

After careful investigation, it was considered advisable for Dr. Gordon to excise the entire circumference of the anus down to the sphincter muscle and dissect out all the mucous membrane and diseased tissue of the lower end of the rectum upward to the extent of two inches. This done, bleeding controlled, and the surfaces cleansed with hot water, the edges of the mucous membrane, or, as Allingham says, the stump of the rectum, was then drawn down and attached to the skin of the anal opening with twelve silk sutures.

The treatment then instituted consisted of a hypodermatic injection of one fourth of a grain of morphine every six hours, and five grains of quinine every six hours. I had the wound cleansed every six hours with tepid water, and dusted the surface with iodoform. At the end of the first twenty-four hours her pulse was 95, her temperature 98.5° F., and she was perfectly comfortable and cheerful. Much the same line of treatment was persevered in for three days, and then gradually discontinued. The sutures were removed on the fourth day, when it was found that partial union had taken place, and that the general appearance of the wound was most satisfactory. At the end of the first week her bowels were moved by the use of the solution of the citrate of magnesium and an enema of warm water. The first movement was attended with some pain and slight bleeding. Afterward her bowels were kept slightly relaxed, and the movements were almost painless. She steadily improved in general health, at the end of two weeks she began to sit up, and, in a few days more, moved about her room at pleasure. After contraction and healing had advanced to some extent, she found that she had good control over her anus, and this we expected, because the sphincter-ani muscle was not injured or involved. During the operation the mucous membrane and sub-mucous tissues were simply dissected off, leaving the muscle intact.

Six months have now elapsed since the operation, and the results have been most gratifying. She has gained in appetite, color, flesh, and strength, and is entirely free from pain. The

‡ Read before the Cumberland County Medical Society.

movements of her bowels are almost painless, but at such times she generally notices a few drops of blood. To the touch the rectum seems perfectly healthy. There appears to be a point of slight abrasion at the ano-rectal junction which looks as if it might be the place from which the few drops of blood oozed.

REMARKS.—The cause of epithelioma of the ano-rectal region is as yet unknown. It is now generally admitted that the disease is of local origin, but just what initiates the changes in cell structure has ever remained past finding out. In regard to the development of epithelioma in other cutaneo-mucous surfaces, as the lips, it is believed that local injuries act as a powerful factor. Thus, it is admitted that a blow, or a fissure, or pressure, may cause epithelioma of the lips and mouth. Reasoning from analogy, it is not improbable that the irritation of fecal material, or hæmorrhoids, or an anal fissure, may excite an abnormal increase and extension of the epithelial cells of the ano-rectal surfaces.

The microscope has plainly revealed that the initial point of the disease is in the vague line between cutaneous and mucous surfaces. Accordingly, the elder Gross says that "epithelioma consists essentially of an ingrowth of epithelial cells into the deeper tissue," while Van Buren adds his authority by saying that, "when epithelioma begins within the rectum, it takes its origin in the follicles of the mucous membrane, and consists of cylindrical epithelial cells." Formerly it was held that epithelioma was caused by some hidden hereditary tendency, but the analysis of many cases has shown that it is as liable to occur in those who are free from such inheritance as it is in those who have a family predisposition. Modern pathologists adopt the theory of local origin, and base their reasons on the facts that the disease can be seen to start at a certain point, and that, when early and radically removed, the eradication is often complete and permanent.

Epithelioma of the ano-rectal surfaces may occur at any period of life, but is thought to be most common after middle life. I have seen three cases of malignant disease of the anus and rectum, and in each instance the patient was under thirty-five. Two of these were females; both were attacked when in good average health, and neither of them had an hereditary tendency toward cancerous disease. "My opinion is," says Professor Gross, "that epithelioma in both these localities is much more common in young persons than is generally supposed. It is not known what influence, if any, sex exerts upon the production of primary carcinoma here; the prevalent belief is that it is most frequent in the female, but this is opposed to my experience, which has supplied me with a much larger number of cases in the male."

The presence of epithelioma of the ano-rectal region is manifested by subjective symptoms and physical signs.

The subjective symptoms during the early stages bear a close resemblance to those of hæmorrhoids. "In the epithelial form it is at first supposed to be hæmorrhoids" (Agnew). "When it does come down to the anus it is generally mistaken for piles" (Allingham). "At the first interview, a patient with cancer will almost always represent himself as suffering from piles" (Van Buren). The patient suffering thus will almost invariably complain of pain. At first it may be only slight and attributed to the irritation of

the anus by the passage of fecal material. Further on it becomes more constant, being stinging or lancinating. In all cases pain is markedly increased during defecation. Cases still more advanced are characterized by pains which extend into the sacrum, perinæum, buttocks, and thighs. Constipation is another symptom almost invariably present. It was the first symptom to attract attention in the case reported above, and in this instance it was so obstinate as to require a daily use of purgatives. In many cases the constipation is due to obstruction, but in this instance the rectum proved to be even over-roomy. Van Buren refers to such conditions, and says that there seems to be defective contractile effort in the muscular walls of the intestine above the seat of the disease. I will place bleeding among the subjective symptoms, because it is one more often described to the physician than observed by him. Loss of blood is usually complained of as an early and quite constant symptom. The quantity may be slight, occurring only when the patient is at stool, or it may be more profuse, oozing either constantly or at intervals. After ulceration has taken place, mucus, or muco-pus, or ichorous fluids, may be mixed with the flow of blood, thereby changing its appearance from the bright arterial blood of hæmorrhoids.

Thus the complaint of a patient that he or she is suffering from "piles"; pain in the ano-rectal region, gradually growing worse from a slight irritation and uneasiness to constant, sharp, burning, lancinating pains; persistent, obstinate constipation, with, perhaps, tenesmus; the history of loss of blood at stools or at intervals between stools, or the loss of material having the appearance of a mixture of mucus, pus, and blood—all of these complete an ensemble of subjective symptoms well calculated to suggest the presence of epithelioma of the anus or lower portion of the rectum.

The physical signs of epithelioma are generally well marked, but vary in different cases. During the incipient stage there may be nothing more upon the mucous membrane than here and there papillary eminences and circumscribed areas which appear thickened and roughened.

Further on, these eminences become higher, vascular, coalesced, and the thickened portion partakes more of induration. Later still, the tissues of the rectum are more thickened and the surface of the growth shows a tendency to become nodular, spongy, fungoid, or cauliflower-like. It has been said that, in the early stages, the finger will detect patches or growths presenting a granular, tuberos, or nodular feeling, with more or less solidity or hardness; or, if polypoid or fungating, their surfaces may be lobulated or warty, cauliflower-like, and friable, so that fragments may be readily detached (Van Buren).

We are warned, besides, to be careful and differentiate between epithelioma and irritable ulcers, benign strictures, syphilitic ulcerations, and hæmorrhoids, but the special points in diagnosis I will not take time to discuss. After the disease is well advanced, the deeper tissues being infiltrated and indurated, and the mucous surface covered with a fungoid growth having a tendency to ulcerate, bleed, and cause a burning pain most of the time, all symptoms and signs are obvious and practically unmistakable.

The results of the early and radical surgical method, as adopted in this case, for treating epithelioma of the anorectal region, has much to commend it to the profession.

1. In the first place, if the operation is performed during the early stage of the disease, the patient is not subjected to very great risk, either from loss of blood, shock, septicæmia, or peritonitis. Therefore, conditions of great danger, which are esteemed justifiable objections to surgery of the rectum by many surgeons, are largely obviated. Heretofore, in many instances, malignant disease of the rectum has been allowed to advance until the deeper tissues became invaded and the constitution involved, and, under such conditions, operative procedures were attended with great difficulty as well as frightful risks of the nature before mentioned.

2. The operation, as performed in this instance, has the very great advantage of preserving the sphincter-ani muscle intact. After the paralysis of the muscles, incident to thorough dilatation of the rectum, has passed away and the parts have healed and contracted, the patient has good control over the anal orifice, and experiences but little trouble when defecating. In some instances, where the disease is well established, it is necessary to sacrifice a portion or all of the sphincter muscle, but, if it be possible to save some or all of it, the benefit to the patient is unspeakable.

TWO CASES OF TUMOR OF THE RECTUM.*

By CHARLES B. KELSEY, M.D.

CASE I.—RECTAL POLYPI.—The patient in this case was a physician, aged about thirty-five years, who for fifteen years had suffered severely from what he supposed to be hæmorrhoids. At each act of defecation there was a good deal of bleeding, and a mass protruded from the anus which could only be replaced with the greatest suffering. So severe was this pain that the movement of the bowels was always dreaded and postponed as long as possible.

Examination.—Immediately after straining at stool two distinct tumors were seen to be extruded and firmly held by the grasp of the sphincter. One was of the size of a hen's egg, the other of about half that size; both were hard and fibrous to the feel; neither showed any trace of mucous membrane on its surface, but, on the contrary, both were grayish and eroded, without the appearance of superficial vascularity. They were described by the patient as bleeding freely at times in small jets when thus prolapsed. Each tumor was attached by a firm, strong pedicle well inside the sphincter, one posteriorly and one on the side, the pedicle of the larger growth being of about the size of the little finger. Combined with these there were hæmorrhoids and fissures, and all the parts were so sensitive that a satisfactory examination could hardly be made.

Under ether both tumors were removed by ligaturing and cutting the pedicles. A third smaller one, of the size of an almond, was also discovered above the sphincter and removed. A microscopic examination showed them to be fibro-sarcomata—in other words, the ordinary fibrous polypi of the rectum; and the chief interest in the case is their

unusual size and number. The patient made a satisfactory recovery.

CASE II.—CANCER OF THE RECTUM; OPERATION; DEATH.—

The patient was seen by me in consultation with Dr. John Cooper, of Brooklyn. He was a man fifty-five years of age, slightly built, somewhat emaciated, and feeble from the effects of his disease, having lost about twenty-five pounds in weight within a year. His symptoms dated back eighteen months, and were the usual ones pointing to cancer or severe ulceration of the rectum—pain, and frequent bloody and mucous passages.

An examination showed a soft cancerous mass of about the size of a large hen's egg projecting into the rectum from the anterior wall, and attached opposite the base of the bladder above the prostate. The growth was lobulated and somewhat pedunculated, hanging free in the rectum, which it nearly filled at that point. The pedicle was not very distinctly marked, but was sufficiently so to give hope of easy removal. A careful examination was made of the left iliac fossa through the abdominal wall, and nothing else was found. The case seemed a particularly favorable one for partial excision, and that operation was consequently performed.

The rectum and anus were first divided with Paquelin's cautery in the median line posteriorly to allow of access to the tumor and of free drainage after its removal. The growth was thus well exposed, but found to be so soft and friable that it was difficult to get a sufficiently firm hold upon it to exert any traction. The wire of an écraseur was therefore passed over it and it was cut off *in situ*. When the instrument came away, bringing the tumor with it, it seemed to me that the end of my index-finger entered the peritoneal cavity at the *cul-de-sac*, but the sensation was so deceptive that I could not be certain, and a subsequent careful examination failed to find any such opening. After the removal of the first tumor a second small mass could be felt above, and this was scraped out as thoroughly as possible, but not entirely removed. There was no bleeding during the operation, and no dressing of the wound was considered necessary. The after-treatment of the case devolved upon Dr. Cooper, and the history is thus given by him:

The patient came out of the ether well, but, about five hours after the operation, there began to be signs of hæmorrhage, and the rectum was tamponed with cotton soaked in Monsel's solution. This failing, injections of very hot water were resorted to, and, after they had been effectual, the rectum was filled with dry cotton. Seventeen hours later this was removed and the rectum injected with carbolized water. Thirty-six hours after the operation the patient began to show signs of failing, and death occurred in fifty-three hours.

At the autopsy, made by Dr. Cooper and Dr. Ray, considerable blood was found in the cavity of the peritonæum; there was a perforation of the rectum at the site of the operation, and there was considerable cancerous deposit along the bowel for six inches above the portion which was found and removed.

The death in this case was due to shock, and the wound of the peritonæum probably contributed to the fatal result by adding to the severity of the operation. A careful examination of the growth after removal failed to show any trace of peritonæum on its surface, and the serous membrane was probably involved in the cancerous disease at the point of injury. Although every arrangement had been made for sewing up the peritonæum in case it should be opened, particular care was taken to avoid wounding it; yet it was wounded, and the small wound escaped detection—as it may easily do. Had it been found and closed, I

* Being, with additions, the reports of two cases related at the meeting of the New York Clinical Society, held February 22, 1884.

doubt if the result would have been any different. It is a complication which must always be looked for in the removal of disease as high up the bowel as this was, and a number of cases go to prove that a small opening in the dependent part of the sac may safely be left to nature to close. The case seemed one of the most favorable ones for operation I have ever seen, and yet the operation ended unfortunately, and the amount of disease undiscovered higher up the bowel would have effectually prevented any good result.

A NEW METHOD FOR THE REMOVAL OF LARYNGEAL GROWTHS, WITH AN ILLUSTRATIVE CASE.*

By WILLIAM CHAPMAN JARVIS, M. D.,

LECTURER ON LARYNGOLOGY AND DISEASES OF THE THROAT IN THE MEDICAL
DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

It may appear presumptuous, at this late day, for any one to offer a novelty in a department of laryngology so extensively developed and upon a theme so well worn as that pertaining to laryngeal neoplasms, and this, too, before a body of experts skilled in the knowledge and practice of the various methods employed for their removal. Any hesitancy, however, on this score has been dismissed through personal conviction, based upon accumulated evidence, indicating the utility and in some respects the novelty of my method, re-enforced by a special request to introduce the subject for your consideration and criticism.

My remarks will be confined to the employment of chromic acid for the removal of laryngeal papillomata. The success which has attended the use of this escharotic in my hands has encouraged me to relate my experience and invite a fair trial in accordance with the rules laid down in this paper.

Of the several principles employed for utilizing the destructive activity of caustics, that of direct fusion has been adopted.

The truism that the result obtained from a given drug often depends upon the exact manner of its employment especially applies to chromic acid in this connection. Its crystals are fused upon the point of a probe, in contradistinction to grooves, cups, etc. Its usefulness depends upon the affinity of the salt for moist papillomatous tissues. These tissues are effectively attacked and removed by this escharotic with unvarying constancy. The crimson chromic-acid crystals, so called, are, more properly speaking, a trioxide of chromium, CrO_3 , its combination with water forming the acid CrO_3OH ,† which is immediately reduced in the presence of organic matter, the resultant salt being the sesquioxide of chromium, Cr_2O_3 .

Chromium trioxide is highly deliquescent, immediately dissolving when applied to moist papillomatous tissues in small quantities. I shall, in deference to general usage, designate the salt chromic acid. The organic matter is apparently dissolved by the oxidizing action of the acid, but,

when applied to a limited area, its action ceases with the conversion of the salt into the chromium sesquioxide, which, as regards organic matter, is an insoluble and inert salt. This self-limiting action is a characteristic possessed by few of the other escharotics, and renders its application as a caustic safe, painless, and yet efficient.

Although chromic acid applied in small quantities at short intervals is capable of exerting a marked progressive destructive effect upon papillomata, its action upon the normal laryngeal mucous membrane is feeble and of brief duration. Its restricted activity in this respect constitutes an additional recommendation as indicating the perfect safety with which it can be carried into the cavity of the larynx.

A pronounced opinion against the use of chromic acid exists in the minds of some laryngologists. This feeling is well expressed by Dr. Morell Mackenzie, in his celebrated work on "Laryngeal Growths," in the following sentence: "Since 1862 mechanical methods have almost entirely superseded the local application of caustics."* In a subsequent paragraph he includes chromic acid in the list.

That such a prejudice should exist does not seem surprising when we consider the manner of its employment by certain operators. Every other consideration seems to have been sacrificed to obtain the speedy action of this and similar escharotics. As a consequence, most of the instruments devised for the laryngoscopic manipulation of chromic acid are arranged to contain the salt in large quantities, as, for instance, Tobold's, Türk's, and Mandl's applicators, Navratil's platinum cup, Fauvel's pinnette, etc.

Hence we find some authorities pronounce unsparingly against the use of the salt applied in substance to papillomatous tissues; others advise it, but warn the operator of the constant suffering following its application to the larynx; and, again, others recommend escharotics only after a preliminary tracheotomy.† In opposition to these views, Lewin goes so far as to always recommend the trial of cauterization for the removal of *small laryngeal growths* before resorting to cutting instruments, claiming that even in the event of failure no harm results, and that the throat by this practice better tolerates the employment of other instruments. Special writers, however, seem more inclined to limit the employment of the salt to the secondary purpose of preventing the reformation of laryngeal growths.‡ It is therefore evident that the salt, when used alone, subserves a double purpose—namely, *it enucleates the growths and prevents their recurrence*.

The recognition of the fact that benign papillomata, in their regrowth, sometimes assume the character of a veritable epithelioma,* enhances the value of chromic acid as an anti-repulsive agent. Although chromic acid and nitrate of silver, developed among laryngoscopic methods side by side, have been indiscriminately employed to obtain identi-

cal results, their action as escharotics has been shown to be dissimilar. A peculiar irritating action exerted by the silver, resulting sometimes in an actual increase of tissue,* is not possessed by the chromium salt. Furthermore, nitrate of silver has a tendency to spread when applied to mucous membranes.† The most important difference, however, between chromic acid and nitrate of silver is the deliquescent character of the former, compared with the more tardy solubility of the latter, in the presence of moisture.

The introduction and employment of chromic acid for the removal of abnormal tissue formations is by no means recent. The late Dr. J. Marion Sims, who was present on an occasion when my method was employed, remarked that he had used chromic acid as a caustic in the early part of his professional career.

As has been already hinted, my plan is to *apply chromic acid in small quantities at short intervals*. This is best accomplished by means of a probe upon the point of which a tiny crystal of the salt has been fused. The probe should have a correct laryngeal curve. Its point, previously heated, is applied to a particle of the chromium crystals about as large as a millet-seed, or, speaking more precisely, a quantity varying in the neighborhood of one sixth of a grain. The crystals fuse and adhere to the heated metal, giving off chromium fumes. This fuming, which might result in the reduction or evaporation of the melted crystal, should be quickly interrupted by placing the probe near the palm of the hand and vigorously blowing upon it. The firmly adherent red bead is distinctly visible upon the dark surface of the chilled probe, and can only be displaced by vigorous friction.

As soon as the patient has properly withdrawn the tongue, the laryngoscopic mirror is placed in position and steadied against the side of the mouth. The probe, grasped in the operator's right hand, is pressed against the opposite side of the mouth, and, with this point as a fulcrum, is steadily advanced over the tongue until its point appears pictured in the laryngoscopic mirror. The angle of the laryngoscope is gradually altered as the applicator advances, in order to keep the probe's point constantly toward the center of the mirror. When the red dot on the probe's point is observed to be almost in contact with the growth, it is suddenly projected upon it by gently depressing the handle of the applicator. The chromium crystal vanishes from the end of the probe, reappearing as a minute white speck upon the point of application. This eschar soon assumes a yellow hue, growing darker as it gradually exfoliates. The sphacelated fragments are expectorated, leaving minute depressions upon the surface of the growth. In this way the papillomatous tissue is removed piecemeal. The irregular projections resulting from this chiseling process are leveled by successive applications of the acid, and all the parts can be carved with the caustic, according to the operator's fancy. The curve of the probe has much to do with its proper manipulation, since its successful introduction into the larynx depends more upon precision than dexterity. As the caus-

tic is guided to its goal by directing the end of the probe, the wire should be curved to keep this objective point constantly in view. A circumferential curve accomplishes this most efficiently, the point of impingement being the intersection of the radius with the arc of a circle at the base of the quadrant. Thus the instrument is readily directed by a simple curvilinear motion. A curvilinear bend, however, is not adapted to every laryngo-oral axis; in these exceptional cases the ordinary elbow-angle must be adopted.

The use of the uncovered probe is sometimes attended with more or less difficulty. This difficulty is principally due to the unintentional deposit of the application upon the base of the tongue and the neighboring structures, or to involuntary closure of the glottis. Both of these obstacles have been overcome by the little instrument shown in Fig. 1. It accomplishes the first indication by protecting the chromium crystal until it reaches the point of application, and the second by surprising the larynx.

The instrument consists of a cannula containing a movable metallic rod, the latter being continued in the form of a spiral spring at the curved portion of the tube. A probe-pointed piece of wire is riveted to the extremity of this spiral to preclude the possibility of the accidental displacement and lodgment of the caustic-carrier in the larynx. The spring also serves as a buffer to deaden the force of the probe's impact against the growth.

The handle of the applicator is excavated to receive a spiral spring, acting upon the movable rod. A detent, *d*, drops between the teeth, *t*, and sets the spring. The nut, *n*, serves to regulate the tension of the spring. When not in use, the stylet, *s*, projects beyond the hood, thus permitting fusion of the chromium crystals upon it as with the ordinary probe.

When ready for use, the probe's point is drawn within the tube by traction upon the milled nut, its return being prevented by the catch. The applicator can now be introduced without risking the loss of the application upon accidental points of contact.

It is not necessary to carry the end of the instrument directly upon the growth, since the probe-point is propelled some distance beyond the end of the tube, thus bridging over the interval of alarm.

A special feature of the instrument is the trigger device. This contributes the utmost steadiness, and, therefore, precision in manipulation, by securing instantaneous action with the smallest expenditure of force. The extremity of

† Türck, "Klinik der Krankheiten des Kehlkopfes," p. 564.

the probe is made of flexible metal, to permit its fixation at any angle. Mr. W. F. Ford, of Caswell, Hazard & Co., is the original manufacturer of this instrument.

The general utility of this method for the treatment of laryngeal growths is apparent when we reflect that more than fifty per cent. of their number are papillomatous in character.

I have entered somewhat minutely into the details of my operation, more to prevent failure due to their neglect than from any personal inclination.

Illustrative Case.—In January, 1882, I met Miss F., thirty years of age, of Norwalk, Conn., in consultation with Dr. R. G. Nolan and Dr. E. R. Reilly.

The patient first noticed her voice to be affected in October, 1881. The hoarseness and difficulty in breathing slowly increased, and, at the time of our examination, she spoke in a strained and scarcely intelligible whisper. We

FIG. 2.

FIG. 3.

discovered by laryngoscopy that the lumen of the larynx was almost entirely occluded. The laryngeal ventricles were obliterated, and the mass, as was afterward shown, projected far within the cavity of the larynx. It presented the usual appearance of a papilloma.

Fig. 2, copied from a sketch, gives an idea of its size and shape. The dark triangular outline near the right arytenoid prominence marks the only available breathing space. A tentative test, made with a probe, provoked a most intense inspiratory spasm, the intervals being prolonged almost to the point of suffocation.

Subsequent experiments resulted in similar manifestations. The patient would not listen to a proposition involving tracheotomy.

While in this dilemma, the idea occurred to me of utilizing chromic acid as an escharotic, applied frequently and in small quantities. The acid was therefore made use of in the manner explained.

I was at once reassured by the good behavior of the larynx. The gentle touch of the probe, laden with the chromium salt, produced neither cough nor spasm.

Applications were made daily, sometimes two or three at each sitting. The respiratory chink gradually widened under the eroding action of the escharotic, and on February 14th the discordant whisper was replaced by a loud, raucous voice. This effect was really accomplished in five days, there being an interruption of nine days, for which the patient was not responsible.

Fig. 3 represents the appearance of the growth on February 22d, shortly after the return of the patient's voice.

Fig. 4, copied from a sketch taken just after the completion of the treatment, March 3, 1882, exhibits the irregularly cicatrized ventricular bands, and the shape and size of the

supra-glottic aperture. At this time the patient claimed she spoke and sang as well as ever.

FIG. 4.

FIG. 5.

Fig. 5 was photographed from a sketch taken March 4, 1884, two years after the completion of the treatment. It shows the relation of the true cords and ventricular bands, and the slight changes of a beneficial character which occurred in that time.

I do not wish to be understood as confining myself to this measure for the removal of all laryngeal papillomata, although it was the only one employed in the case described. On the contrary, I have not hesitated to employ it in conjunction with the forceps or snare. I believe that a majority of those present will agree that, in view of the facts just given, the opprobrium attached to this beneficent measure is unjust, and largely due to misapprehension or misuse.

No observations can be said to have acquired the honor of established facts until they have been verified by long-conducted and repeated experimentation. I have endeavored to constantly keep this in view while formulating these results, being well aware that bare assertion based upon insufficient data is scientifically valueless.

Conclusions.—In recapitulating, I submit the following propositions:

1. Trioxide of chromium, or so-called chromic acid, is valuable as an escharotic on account of its self-limiting action.
2. It affords a safe and reliable means for the removal of large and small soft laryngeal growths.
3. It not only removes the growth, but also prevents its recurrence.
4. It is best applied fused upon a probe.
5. Its application is facilitated by an instrument devised to act as a guide, protector, and regulator.
6. Its use in the larynx is not necessarily attended with pain or spasm.
7. It offers a substitute for tracheotomy and thyrotomy in certain cases where these measures have been adjudged necessary.

25 EAST THIRTY-FIRST STREET.

DISCUSSION.

Dr. COHEN.—It is so long since I have employed the agents mentioned in the treatment of these affections of the larynx that I have almost forgotten the fact. Everything depends upon the manner of making the application, and Dr. Jarvis's paper will give us confidence in trying the method again. The results of old methods certainly are not very encouraging. In a case like the one described I think the forceps should be applied and as much as possible of the growth removed, after which the caustic should be applied. But even then I should

not expect to get such quick results as Dr. Jarvis has obtained with the caustic alone.

Dr. ROE.—I have used the caustic, but have not attempted to remove the whole of the growth by that means alone, as Dr. Jarvis has done. An interesting case of papilloma of large size came under my observation about a year ago. The patient had been aphonic about eight years, and her physician had treated her for chronic hoarseness. I found a papilloma occupying the anterior two thirds of the right vocal cord. This I removed in part with the forceps, and afterward she could speak fairly well. At the next sitting I removed the whole growth except the base, to which I applied the chromic acid.

Dr. ROE and Dr. SEILER described an instrument similar to the one mentioned by Dr. Jarvis, which they had used in the removal of these growths.

Dr. INGALS also described an instrument which he had employed for making applications to the larynx. He had used chromic acid in cases of cancerous disease without any bad result.

Dr. G. W. MAJOR, of Montreal.—I think the principle of treatment of growths by means of chemicals depends upon their affinity for water. It is necessary to use them in small quantities and with much care, as they are difficult to handle. Indeed, in children it is almost impossible to employ them at all. For a year I have been in the habit, in the case of children, of making applications of absolute alcohol to the growth by means of the spray, and the results have been very successful, resulting irritation being but slight, while the tumor has been caused to shrivel.

Dr. JARVIS, in closing the discussion, said: Instrumental interference in my case was out of the question because of the danger of spasm of the glottis. The seriousness of this accident is likely to be in proportion to the size of the laryngeal growth, and to depend somewhat upon its location. If it extends some distance into the larynx, the removal of the upper portion of the growth would simply produce intense spasm and possibly suffocation. If the location and size of the growth were such as to make the occurrence of spasm improbable, I would not hesitate to adopt the method suggested by Dr. Cohen.

CASES OF RESTORATION OF THE EYELID BY TRANSPLANTATION OF A FLAP WITHOUT A PEDICLE.*

By CHARLES STEDMAN BULL, M. D.,
NEW YORK.

CASE I.—The patient was a man, aged thirty-two, with complete ectropion of the right upper lid, and entire destruction of the right lower lid and eyeball from a burn. The accident had occurred fourteen months before, hot molten metal having been dashed in his face from a ladle. The whole forehead, temple, and cheek were a mass of cicatricial tissue, the lines of contraction running in almost every direction; and this rendered impossible any attempt at restoring the eyelids by sliding or twisted flaps. Wolfe's method of transplantation without pedicle was deemed the only one applicable to the case, or that gave any promise of success, and the patient consented to the trial being made.

The ciliary margin of the upper lid was loosened from its cicatricial attachment to the eyebrow and brought down into its normal place, and was then stitched to the edge of the skin which corresponded to the position of the ciliary margin of the lower lid, and which was adherent to the inferior orbital mar-

gin. A piece of skin, one third larger than the space to be filled, was then marked out on the inner side of the left forearm, and carefully dissected up, leaving, however, an attachment by a narrow pedicle. The space to be filled was then prepared by cleaning the surface and stanching the slight flow of blood. The pedicle of the flap was then divided, and the lower surface of the flap carefully cleaned of all fat and connective tissue. It was then placed in position, and one end, that seemed very redundant, was trimmed off. The transplanted flap then measured an inch and three quarters in length by an inch and a quarter in breadth. One suture was inserted at each end of the flap, and then the entire external surface was covered with a single layer of goldbeater's skin and five layers of iodoform gauze; over this a layer of borated cotton was applied, and then a roller bandage. The dressings were not removed for five days. They were then carefully taken off, and the flap was found united throughout *except at the points of suture*. There had been no suppuration. The same dressing was reapplied and changed every second day for two weeks, and then was discontinued entirely. The flap has shrunk somewhat, and the patient is able to open the eyelids to about two thirds of the normal width. It is now six months since the operation was performed.

CASE II.—This patient was also a man, aged forty-one, a fireman by occupation, who had been burned on the left side of the forehead and nose, and on the left upper eyelid, two years before I saw him. The inner two thirds of the upper lid were everted and anchored to the upper orbital margin. The forehead, nose, and cheek were so badly scarred that there was no hope of any successful result from sliding or twisted flaps. The everted lid was dissected free from the orbital margin, brought down into place, and stitched to the margin of the lower lid, the edges of both being first freshened. A piece of skin, one inch long by three quarters of an inch wide, was then dissected up from the inner side of the left forearm and carefully cleaned of all fat and connective tissue, leaving it still attached by a narrow pedicle to the arm. The space to be filled was prepared for its reception by careful cleansing and the removal of all small clots and shreds of tissue. The pedicle was then divided and the flap transferred to the vacant space to be filled. As it did not lie quite smoothly, owing to the cicatrices on the side of the nose, six fine sutures of carbolized silk were introduced at different points, in order to maintain the flap in position. This was then covered by a layer of goldbeater's skin; over this were applied four layers of iodoform gauze; over this a layer of borated cotton and a roller bandage. The dressing was not disturbed for four days, and when it was removed there were several suppurating spots at the suture-points. The wound was carefully washed with a one-per-cent. solution of carbolic acid, and the dressing then reapplied. This was changed and the surface carefully washed, as before, every day for ten days. By this time all suppuration had ceased, the flap had united throughout, and there was no slough.

CASE III.—The patient was a man, aged twenty-three, with complete eversion of the right lower lid from caries and long-continued suppuration of the inferior orbital margin and malar bone. The patient was a marked example of scrofula, and bore the traces of glandular suppuration on both sides of the neck and beneath the angles of the jaw in deep scars. There had been since boyhood a carious process in the malar bone on the right side, with a fistulous opening leading down to the diseased bone, and from time to time small pieces of bone had come away. No operation had ever been done for the removal of the dead bone and the cure of the disease. Gradually the lower lid had become everted until the entire lid margin appeared bound down to the margin of the orbit, or rather to the

* Read before the American Ophthalmological Society, July 16, 1884.

malar bone, and the eversion was complete. The fistulous opening had closed about a year before I saw the patient, and had remained so ever since. There was constant epiphora, and occasionally a slight muco-purulent discharge. The palpebral conjunctiva was very much thickened, and presented a surface like that in chronic granulations or trachoma. The site of the old fistulous opening was a little to the nasal side of the malar prominence, but the bone disease had been so long-continued that the periosteum had become involved for some distance on all sides, and nearly the entire lid was bound down firmly to the underlying bone, in which there was a perceptible depression caused by loss of substance. The skin covering the cheek and temple was scanty in quantity and but very slightly elastic, so that it was not deemed advisable to attempt filling in the space by a sliding flap from the cheek or a twisted flap from the temple; but it was thought that the best results might be gained by filling the vacant space with a flap of skin taken from a distance by Wolfe's method, although it is well known that this method of operating does not succeed so well in cases of restoration of the lower lid as where the upper lid is to be restored, mainly owing to a lack of sufficient base-support for the transplanted flap.

The depressed cicatrix was first separated from its subcutaneous adhesions to the bone with a tenotomy-knife, introduced through healthy tissue beyond the margin of the cicatrix. This required some little time and careful manipulation, owing to the extent of the adhesions. It was then found that, though the tissues were more movable, the depression and eversion of the lid were as marked as ever. The next step was the excision of all the cicatricial tissue, the first incision being made parallel and very close to the ciliary margin of the lid, throughout its entire length. The lid was thus made freely movable, and was replaced in position. The cicatricial tissue was then carefully excised, and this left a space an inch and a quarter long by half an inch wide, to be filled by a transplanted flap. This was marked out on the thin skin covering the anterior wall of the thorax on the right side, the measurements being a quarter of an inch larger in all directions than the space to be filled. This flap was then dissected up free from all adipose and connective tissue, and carefully fitted to the space in the lower lid, which had been previously prepared for it. A little trimming of the edges was found necessary before complete coaptation succeeded. As this was the lower lid, with not a very firm base of support, it was thought best to introduce a few sutures to maintain the parts in coaptation, and five stitches of fine carbolized silk were introduced at regular intervals and tied. The flap and surrounding skin were then gently and carefully cleansed with a saturated solution of boric acid, and the entire surface was then covered, as in the other cases, with a layer of goldbeater's skin, which extended for the distance of an inch on all sides beyond the line of the flap. Over this were applied four layers of iodoform gauze; over this a layer of borated cotton, and then a rather firm roller bandage.

The patient was quite prostrated from the effects of the ether, as the operation took about forty-five minutes, but rallied in a few hours and sank into a quiet sleep. The next morning he was very comfortable, and complained of no pain. The dressings were not removed till the afternoon of the third day, when the patient complained of a sense of hardness and discomfort in the eyelid. When the flap was exposed it was found that there was suppuration at all the suture-points, and the surface of the transplanted skin had a brownish discoloration, as if about to slough. The parts were thoroughly cleansed with a two-per-cent. solution of carbolic acid, and freely dusted with iodoform. The goldbeater's skin, iodoform gauze, and borated cotton were then reapplied, and over all a rather loose

roller bandage. This was allowed to remain for two days, and when it was removed it was found that there was a complete slough of the epidermal layer of the flap, but that the necrotic process had not extended any deeper. Suppuration still continued at three of the suture-points, and a small amount of pus exuded on pressure, but the flap was quite firmly adherent. The parts were again cleansed with a two-per-cent. solution of carbolic acid and covered with powdered iodoform, goldbeater's skin, and iodoform gauze, but without the layer of borated cotton, and a loose bandage was applied over all. This dressing was changed and reapplied every day, the parts being carefully cleansed as before.

From this time suppuration ceased, and the healing process went on steadily to completion. The sutures were all removed on the sixth day. It is now nearly three months since the operation, and, though the process of shrinkage in the flap has not yet ceased, the result of the operation is very satisfactory.

Book Notices.

Brain Exhaustion, with some Preliminary Considerations on Cerebral Dynamics. By J. LEONARD CORNING, M. D., formerly Resident Assistant Physician to the Hudson River State Hospital for the Insane, etc. New York: D. Appleton & Co., 1884. Pp. 234.

THE author has chosen an affection of which many examples are to be found if we can accept as true the statements made by late writers on the subject of diseases of the nervous system. Certain it is that every practitioner is called upon to prescribe for patients giving such symptoms as Dr. Corning describes in this little book. The author gives some preliminary considerations on cerebral dynamics, a confessedly dry subject, but made as interesting by the author as the study of the osseous system by the medical student. Much credit is given the late Dr. G. M. Beard for his researches in the same line. The author shows familiarity with the literature of the subject, and has evidently given much attention to what he calls "the dynamic forces and the brain." The chapters devoted to the clinical and pathological consideration of the subject are concise and yet complete. The clinical history is illustrated with the histories of cases. This adds much to the interest and serves to confirm the author's views, and to elucidate what might otherwise be obscure points.

The author inclines to the opinion that diseases of the nervous system are on the increase, and tries to find a cause for this in the accompaniments of civilization and in climatic influences. Rum and tobacco in excess, to state it in the language of the temperance people, play their part. The telegraphic system, railways, steam, the necessary work on the great newspapers, are illustrations of the accompaniments of civilization which predispose to brain exhaustion. Our own country, with its dry and stimulating climate, predisposes to it. False educational conceptions and methods favor it.

Not only do these act as predisposing causes of brain exhaustion, but, in the opinion of the author, they may have some agency in affecting the mental integrity of posterity.

The chapter devoted to mental hygiene is a good one.

The matter of treatment is an important one. The author gives attention to diet, rest, and medication. Electricity is given an important place in the treatment, and the author gives full directions as to its uses and application. He has devised an instrument for compressing both the carotid arteries at the

same time, and he thinks he has seen much benefit from the combined use of this compression and galvanization of the cervical sympathetics.

The book is written in a pleasant style, contains much valuable matter, and would be a decided addition to any physician's library. The get-up of the book is admirable.

A Text-Book of Pathological Anatomy and Pathogenesis. By ERNST ZIEGLER, Professor of Pathological Anatomy in the University of Tübingen. Translated and edited for English students by DONALD MACALISTER, M. A., M. B., M. R. C. P., Fellow and Medical Lecturer of St. John's College, Cambridge. Part II.—Special Pathological Anatomy: Sections I–VIII. London: Macmillan & Co., 1884. Pp. xv–371. [Price, \$3.50.]

THE eagerness with which a new work on pathology is seized upon by German students is seen in the fact that three editions of the first part of this work (in the German language) were called for before the second part was ready for the printer. The same ground is covered, of course, which has been covered repeatedly in previous German works on pathology, but this book is in advance of all others in its treatment of the germ theory and its application to special pathology. Lucid and fascinating as the work of the translator is, and commendable in the highest degree, it presupposes also clearness and conciseness of thought and expression on the part of the original work, qualities which are anything but common among German writers. The subjects which are treated of in this volume are the blood and lymph, the vascular mechanism, the spleen and the lymphatic glands, the serous membranes, the skin, the mucous membranes, the alimentary tract, and the liver and pancreas. In the chapter on the serous membranes we notice a radical change, in the adoption by the author of the doctrine of Hertwig and Balfour, that the primitive body-cavity has no original communication with the vascular system, in opposition to the theory of Haeckel, that the pleuro-peritoneal cavity is only a lymph-space. We would also note, as especially satisfactory, the section upon the skin. When this work is finished there will no longer be just cause for the complaint that there is no satisfactory treatment of the subject of pathology in the English language.

Regional Surgery, including Surgical Diagnosis. A Manual for the Use of Students. Part II, the Upper Extremity and Thorax. By F. A. SOUTHAM, M. A., M. B. Oxon., F. R. C. S. Eng., Assistant Surgeon to the Manchester Royal Infirmary, etc. London: J. & A. Churchill, 1884. Pp. xvi–223 to 582, inclusive.

THE first part of this students' manual appeared two years since, and dealt with the head and neck. This, the second, includes the upper extremity and the thorax, and the third will include the abdomen and the lower extremity. Had we chosen the title, we should have reversed it, and called it a manual on surgical diagnosis for the use of students, including some regional surgery, which more correctly represents the work than the name regional surgery. It is a dry sort of "cram-book," such as a student generally carries in his pocket and reads in out-of-the-way places the week before examination. In the place of illustrations there are tables of differential diagnosis, and the whole book is eminently calculated to make the student wish he were something else. For example, on page 136 the student is offered the following interesting reading, the numbers referring to various scattered paragraphs:

"*Tumors of orbit.*

"1. *Those originating in the orbit itself*, connected with either

"Bone, e. g., exostosis (236), enchondroma (237), sarcoma (243).

"Periosteum, e. g., nodes (usually syphilitic, 231), fibroma (238), sarcoma (243).

"Soft tissues of orbit, e. g., sebaceous cyst (207), gummata (239), sarcoma (243), carcinoma (243), hydatid cysts (240).

"Blood-vessels, e. g., aneurysm and pulsating tumors (241), nævus (242).

"Lachrymal gland, e. g., inflammatory enlargement (218), new growths (221)."

We give this simply as a fair example of the style of the book. It is surgery boiled down, surgery destitute of all attraction, and with all grace and vigor of language and description carefully eliminated; and the natural result is a book full of hard, dry, useful facts.

Hand-book of Vertebrate Dissection. By H. NEWELL MARTIN, D. Sc., M. D., M. A., Professor in the Johns Hopkins University, and WILLIAM A. MOALE, M. D. Part III. How to Dissect a Rodent. New York: Macmillan & Co., 1884. Pp. iv–168 to 247, inclusive. [Price, 60 cents.]

THIS third part of Martin and Moale's dissection hand-books describes the necessary manipulations for the dissection of the common rat, with a description of all that the student of comparative anatomy would be expected to observe in carrying out his work. There is little to be said of such a work except that it is compact, complete, and conveniently arranged, and just suited to the purpose for which it was intended—to serve as a manual for use at the dissecting-table. It is well illustrated and carefully indexed.

Transactions of the Obstetrical Society of London. Vol. XXV, for the Year 1883. With a List of Officers, Fellows, etc. London: Longmans, Green & Co., 1884. Pp. lix–315.

A GLANCE at the contents of this volume shows that the London Obstetrical Society, with true English conservatism, has not yielded to the fascination of surgical gynecology to the neglect of the legitimate field of obstetrics. There is a danger, which is already pronounced in certain quarters, that the all-important themes pertaining to obstetrics will languish from want of attention, and from interest having been diverted into another field. With all regard for the merits of Wells, Thornton, Bantock, Tait, and the rest of the British gynecologists, it is satisfactory that the obstetricians Duncan, Barnes, Braxton Hicks, and the others, have not failed in furnishing their just proportion to the Transactions of the Obstetrical Society for 1883.

BOOKS AND PAMPHLETS RECEIVED.

The Theory and Practice of Medicine. By Frederick T. Roberts, M. D., etc., Professor of Materia Medica and Therapeutics, and of Clinical Medicine, at University College, etc. With illustrations. Fifth American edition. Philadelphia: P. Blakiston, Son & Co., 1884. Pp. 1,008.

Diseases of the Throat and Nose, including the Pharynx, Larynx, Trachea, Esophagus, Nose, and Naso-pharynx. By Morell Mackenzie, M. D., London, Consulting Physician to the Hospital for Diseases of the Throat, etc. Vol. II. Diseases of the Esophagus, Nose, and Naso-pharynx, with Index of Authors and Formule for Topical Remedies. Illustrated. Philadelphia: P. Blakiston, Son & Co., 1884. Pp. viii–17 to 550, inclusive.

The National Dispensatory. Containing the Natural History, Chemistry, Pharmacy, Actions, and Uses of Medicines, including those recognized in the Pharmacopœias of the United

States, Great Britain, and Germany, with numerous references to the French Codex. By Alfred Stillé, M. D., LL. D., Professor Emeritus of the Theory and Practice of Medicine and of Clinical Medicine in the University of Pennsylvania, and John M. Maisch, Phar. D., Professor of Materia Medica and Botany in the Philadelphia College of Pharmacy. Third edition, thoroughly revised, with numerous additions. With three hundred and eleven illustrations. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. xv-1755.

LETTER FROM VIENNA.

The Advantage of the Summer Course, for studying Obstetrics.—The Assistants at the Clinics, and their Work.—Billroth's Fourteenth Resection of the Pylorus.—Gastrostomy.—Antisepsis.—A Promising Clinical Teacher.

VIENNA, July 31, 1884.

THERE is a visible falling off in the attendance at the various clinics this summer in comparison with last, the reason of which is not very clear, unless it is that there exists in the minds of some of the American students a certain lurking dread of the cholera. No cases have been reported here, though there have been the usual rumors with regard to their existence. The weather during the past two or three weeks has been delightfully cool, and in every way conducive to hospital work. The few Americans who remain here find that they can employ their time most profitably, especially in the obstetric wards. The writer has already expressed the opinion that summer is the time in which to study midwifery in Vienna, and he has frequently had an opportunity to verify that statement.

The surgical clinics are conducted by the assistants during the vacation, but they are none the less interesting on that account; on the contrary, the summer visitor can witness just as many operations as in winter, and has a far better chance to observe the various steps closely. It is surprising to see how much is intrusted to the assistants, and yet not so surprising when one observes their skill and the minuteness with which they execute all the details suggested by their chief.

Perhaps the most striking feature of the Vienna school is that those who are trained in it learn one method of working, and one only—that of the professor under whom they have studied. But with this method they are thoroughly acquainted. This may be a somewhat narrow way of educating men, yet it has this important result—the Vienna assistant never hesitates in an emergency, but meets it promptly as he has been taught. He may not always do the best thing, according to our ideas, but indecision does not form one of his failings. This coolness in trying moments will be noticed especially in the surgical and obstetrical wards, where emergencies are of such common occurrence.

It would be manifestly unfair to compare an assistant with one of our average hospital internes. The former is necessarily older, brings a greater amount of maturity to the work, and is expected to assume heavier responsibilities. As he combines with his ordinary routine duties those of an instructor in the university, he must be thoroughly versed in his specialty.

His term of service is from six to ten times as long as that of our house-officers, so that he has an opportunity to become perfectly familiar with the peculiar methods of his chief, and, through constant practice, to acquire a surprising dexterity in

applying them. Instead of being compelled to pick up his experience in a desultory way from attendance on a number of different visiting surgeons, as with us, he is brought into daily contact with *one* teacher—a man of more or less individuality, who desires to stamp his opinions upon the minds of his followers. The practice of the assistant is that of his professor, which the younger man rarely ventures to modify essentially.

Each clinic is an independent school, of which the professor is the central sun, the assistant an orb of lesser magnitude. And yet, with all the German's ability, it is a question if the American interne can not sometimes, by his native ingenuity and confidence in his own resources, extricate himself from a dilemma quite as creditably as the Vienna assistant with his wider experience and strict adherence to established rules.

To characterize the essence of Vienna instruction in a few words: In spite of its dogmatism, it aims at making of the student a man of prompt decision and rapid execution—in short, a practical physician rather than a theorist.

I referred above to the surgical clinics, and this leads me to mention that Billroth performed another resection of the pylorus last week—his fourteenth operation of the kind, I believe.

The frequency with which this formidable operation has been attempted, and abandoned on account of unsuspected complications, has thrown some doubt upon the possibility of deciding beforehand which cases are suitable for resection and which are not.

Gastrostomy for carcinoma of the cesophagus and cardiac orifice is a favorite procedure in Albert's clinic, where I think it has been done upward of thirty times (twice this week), with very fair success in prolonging life. Such a palliative course as this will always commend itself to American surgeons rather than the radical treatment of Billroth.

There is little to be said with regard to Vienna antisepsis in addition to what has been previously stated. The spray is still used in intra-peritoneal operations, at least in the surgical clinics, for it has disappeared from Professor Braun's lecture-room. The solution of corrosive sublimate is extensively used, both in spray and for the irrigation of wounds. As an after-dressing, iodoform continues to be popular, and every one professes skepticism as to the danger of poisoning. Powdered benzoate of sodium is often sprinkled over the external wound in laparotomy previous to applying the dressings. By some it is preferred to iodoform.

Nothing new can be mentioned with regard to the summer courses. Popular classes conducted by assistants are that of Kiehl on the skin, Finger on syphilis, and those on operative obstetrics. Frühwald, at St. Anna's Children's Hospital, gives an interesting course. I have counted in his class representatives of nine different nations (including two Japanese). It is such a cosmopolitan gathering as this which gives one an idea of the wide influence of Vienna in the medical world.

It may not be improper to mention one who, in a quiet way, is acquiring an international reputation as a clinical teacher. I refer to Dr. Joseph Taelg, Bamberger's assistant, whose instruction in general medicine is eagerly sought after by Americans, and perhaps more highly valued than any other which they receive here. A keen diagnostician, a clear yet remarkably simple expounder of his subject, discarding all the complicated apparatus which some clinicians consider so necessary, he has the happy faculty not only of unraveling knotty cases, but of teaching his pupils to do the same. Without any apparent effort to force his students to adhere to any one method of investigation, he only asks of them accuracy and common sense.

Altogether, Dr. Taelg may be regarded as a representative of the best type of the younger Vienna men, with whom personal gain is not the sole consideration.

Edited by
FRANK P. POSTER, M. D.

NEW YORK, SATURDAY, AUGUST 23, 1884.

THE TRANSMISSION OF TUBERCULOSIS BY MILK.

An English physician, Dr. Francis Imlach, has lately made a number of experiments bearing upon the question of the transmissibility of tuberculosis by the milk of tuberculous cows, and has published an account of his observations in the "British Medical Journal." Referring to the positive results obtained in such experiments by Gerlach, Münch, and Bollinger, Dr. Imlach suggests that the idea of there having been some fallacy in their experiments is favored *a priori* by the well-known freedom of young calves from tuberculosis, which could scarcely be the case if the disease were readily transmissible by the milk, and favored further by analogy, since in the case of syphilis, a disease of far more assured infectiousness than tuberculosis, the physiological secretions are still held by the most capable observers to be powerless to convey the infection. The drift of his own experiments supports this theoretical view of the matter, but, while he thinks that they do not suggest the inference that a healthy child in a comfortable house would be hurt by the occasional ingestion of such milk, it would be rash to conclude, without further observations, that tubercle might not thus be engendered in an ill-fed and ill-clad child with an unhealthy heritage and a digestive mucous membrane eroded by frequent diarrhoea. This must certainly be regarded as a moderate way of stating a conclusion.

Three tuberculous cows furnished the milk which was employed in Dr. Imlach's experiments, and three calves, four pigs, a goat, two young monkeys, and fourteen young guinea-pigs (besides one monkey and four guinea-pigs for "control" purposes) were the subjects of the feeding experiments. One of the calves was fed from the 15th of April, when it was a week old, until the 11th of May, upon three quarts daily of the milk from one of the cows, and from the 11th of May until the time of its death, July 14th, upon three quarts daily from another of the cows. A careful post-mortem examination revealed no appearance of tubercle in the lungs, the pleuræ, the liver, the kidneys, the glands, or the other organs; but there was some congestion of the small intestine, which was supposed to be the cause of death, and there were a few small nodules, about as large as a pea, scattered over the mesentery. These, however, had not the look of tuberculous nodules as they are ordinarily seen in mature cows, and microscopical investigation failed to reveal the bacilli of tubercle in any of them. The two other calves were obtained, one on the 14th and the other on the 17th of August, each being a fortnight old and of healthy parentage. They were fed with two quarts of milk apiece from two of the cows until the end of October, when they were slaughtered and

found to be in prime condition, nothing abnormal being discovered on most careful post-mortem examination.

Two of the four pigs were fed with the milk from June 27th until August 20th, and the other two from August 21st until the end of October, when all four of them were killed and found to be absolutely free from disease. The goat, which was of unknown age, got an indefinite quantity of the milk daily from June 11th until the end of October. It was then killed, and its lungs and other organs were found entirely free from tubercle. Two young monkeys, newly landed, were obtained on the 29th of March. One of them was fed on bread soaked in the milk of all the three cows in succession. The other was fed with bread soaked in milk from a healthy cow. Early in June another young monkey was procured, and it was fed like the first. Besides the milk, all of them were given fruit. The "control" monkey died one cold night, after it had been kept five weeks. Its lungs were congested, but there was no tubercle. At the end of October the two other monkeys were killed, being in a miserable condition at the time, and the lungs of both were found riddled with tuberculous cavities, their livers studded with purulent cavities, and their mesenteric glands enlarged. From the great proneness of monkeys to fall a prey to tuberculosis when they are brought to cool climates, Dr. Imlach argues that the results in these two animals can not fairly be considered as due to infection by the milk, and this, we think, should undoubtedly be admitted. The guinea-pigs were fed on bread soaked in the milk, eight of them for a month, and six of them for a length of time which is not clearly stated. Three of them died, and the others were killed, but none of them showed signs of tuberculosis.

In view of the general alarm that has been occasioned by apparent demonstrations of the capability of milk to convey tuberculosis, the results of these observations are certainly to some extent reassuring; but it must be borne in mind that the experiments were few in number, that in such a matter as this it takes an overwhelming preponderance of negative results to raise a well-founded presumption of fallacy in a few positive instances, and that Dr. Imlach was careful to exclude lesions of the udder—an additional source of infection in the case of milk taken indiscriminately from dairy cows. Bearing these considerations in mind, we are unable to realize the safety of relaxing in any respect the precautions that our sanitary boards are beginning to take to prevent the sale of milk from diseased cows.

GYNÆCOLOGY IN THE GENERAL HOSPITALS OF LONDON.

It seems as if it would never cease to be the case that the particular aspect of a matter which, in one community, men of discernment feel impelled to urge upon the attention of their fellows, from its having been ignored, is precisely the aspect which, in a different community, men of the same sort feel it their duty to try to draw down from the false prominence into which it may have been elevated. This state of things is strikingly exemplified in the comparative status of gynæcology, in its relations to general surgery, in the great hospitals of London

and in those of this country—using the term gynecology, in its broad sense, to include both obstetrics and the medical and surgical management of the diseases and injuries peculiar to women, but not necessarily connected with childbirth. Here, what needs to be urged upon the managers of the great general hospitals is the propriety and the advantage of establishing a gynecological department, to be given into the care of one or more men of recognized attainments in the specialty, whose ambition and constant effort would be directed to perfecting its conduct. In London, on the contrary, to judge from our previous understanding of the facts together with the additional light thrown on them by the physician-accoucheur of St. Bartholomew's Hospital, Dr. Clement Godson, in his recent address before the Section of Obstetric Medicine of the British Medical Association, as we find it published in the "British Medical Journal," gynecology is too much specialized, being restrained to an absurd degree from overlapping general surgery in the matter of operations.

Speaking for his own hospital, Dr. Godson informed his hearers that in the year 1858 it was made the rule of the house that the medical officer in charge of the ward set apart for the diseases peculiar to women should not perform any surgical operation on his patients, but that all such operations should be done "by each surgeon in turn, for a period of three months at a time." It is scarcely necessary to add that the "surgeons" are not the gynecological members of the hospital staff. So rigidly was this barbarous rule enforced that in 1859 "Dr. West was severely censured 'for having taken upon himself to perform an operation of a surgical character upon a patient admitted into Martha's Ward.'" But, as if they had not gone far enough in seeking to degrade and humiliate their gynecological officers by taking their proper work out of their hands and distributing it among the surgeons, in 1870 the managers committed it to the fourth surgeon and the first assistant surgeon. Although it is but fair to presume that the fourth surgeon of St. Bartholomew's Hospital is in nothing save rank the inferior of his seniors, it is difficult to avoid the inference that the authorities of the house took no pains to spare their gynecologists the appearance, if not the reality, of a fresh indignity. But it appears that, in its essential features, this state of things is not peculiar to the hospital mentioned, but obtains in many of the older general hospitals of London. The result is that the gynecologists of those institutions either do no operative work or they do it only by the kind permission of their surgical colleagues, and really in contravention of the rules; and the anomaly is witnessed of the very man who is making for himself a world-wide reputation as an ovariectomist, by his success in a special hospital, being debarred from so much as sewing up a lacerated perineum in the general hospital where he happens to hold the gynecological appointment. When we add that these general hospitals are the institutions which also serve as the medical colleges of the British metropolis, and that their professors of gynecology find it necessary to send their students to the special hospitals for practical instruction in that branch, it is evident that the preposterous rule in question works to the

detriment of the general hospitals as educational institutions at the same time that it cripples the progress of gynecology in London. Strictly construed, the rule applies even in the case of operations that are distinctively obstetrical, so that the obstetrician would have no warrant for performing a Cesarean or a Porro operation, as Dr. Godson suggests.

We do not wonder that the gynecologists of London chafe under these galling and discouraging and utterly senseless restrictions, or that, to use Dr. Godson's vigorous expressions, they are driven to feel that the old term of *man-midwife* would fit them better than that of obstetrician.

MINOR PARAGRAPHS.

THE MEDICAL ASPECTS OF THE GREELY EXPEDITION.

STRICTLY speaking, the events connected with the expedition have little to do with medicine, except in the broad matter of the influence of privation, hardships, and mental depression on the vital powers of men subjected to them for a protracted period, and this aspect is so extensive in comparison with the facts at our command that it is not our intention to enter upon its consideration. The formalities that had to be gone through with in order to obtain permission for the body of one of the deceased men to be taken through this city, involving as they did the issuing of a certificate by the chief medical officer of the military department which, although naturally supposed by him to embody nothing but the truth, was in the most essential particular directly at variance with the facts—the inconvenience of these formalities, we should think, would be likely to raise the question in many minds whether, on the whole, it conduces to the accuracy of our records, or indeed answers any important good purpose, to insist upon their being gone through with under like circumstances.

As for the absurd talk about "cannibalism" indulged in by some of the newspapers, it can only be said that the facts, as now understood, and as supported by the post-mortem examination of at least one of the men who perished, make it probable that the flesh of some of the deceased was, more or less of it, consumed as food. But, if this happened at all, it happened under the dire stress of circumstances that can scarcely have been appreciated by the vile horde of howlers who have beset the relatives of more than one of the deceased with their clamors of exhumation, apparently from no better motive than that of the most vulgar curiosity. Moreover, it does not constitute "cannibalism," and the less this term is used in connection with the matter the better will it be for our reputation as a decent people.

A NEWSPAPER ACCOUNT OF A HYSTERECTOMY.

LAST Monday the "World" published a precious mess of bosh about an operation for cancer of the uterus, by extirpation of the organ, performed at the New York Hospital on the preceding Saturday. The name of the operator is given, coupled with the most fulsome laudation, and the details of the operation are spread out without stint. The account closes with this Bunsian forecast: "If no untoward symptoms set in, and the growth does not return, the patient will recover." Disgusting as such stuff ought to be to the "World's" readers, it can not be more so to them than to the surgeon with whose name the writer of the article makes so free. We can not suppose that non-medical persons are intentionally admitted to witness surgical operations at the hospital, and it may be asked if, even at the expense of some inconvenience to those who are really en-

titled to be present, the authorities of the institution would not be justified in enforcing a stricter scrutiny of individuals who may present themselves on such occasions.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending August 19, 1884:

DISEASES.	Week ending Aug. 12.		Week ending Aug. 19.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus.....	0	0	2	1
Typhoid Fever.....	24	7	36	9
Scarlet Fever.....	33	3	30	4
Cerebro-spinal meningitis.....	3	3	1	1
Measles.....	62	14	43	6
Diphtheria.....	26	13	22	14

The Cholera.—Since our last issue the news in regard to the outbreak on the European shore of the Mediterranean has not been so favorable as it was last week. A decided recrudescence has shown itself in Toulon and Marseilles, and the prevalence of the disease has become more marked in a number of Italian towns. Still, it must be said that the epidemic remains within moderate limits, and that the probability is yet considerable of its not attaining the proportions that seemed to be threatened at the outset. On Wednesday there was a rumor that the disease had broken out in this country—in an Iowa town, but the symptoms described in the newspaper reports do not appear to be those of cholera.

Yellow Fever at Key West.—On Friday of last week one of the officers of the United States steamer Galena was admitted into the Marine Hospital, suffering from yellow fever. On Wednesday the patient was reported to be doing well, no more cases had occurred, and, all necessary precautions having been taken, it was thought that the disease would not spread. The Galena sailed for Portsmouth, N. H., on the 16th inst.

The Society of the Red Cross.—At the International Congress, to be held in Geneva, Switzerland, on the first of September, the United States will be represented by Miss Clara Barton.

The International Medical Congress, it has now been decided, will hold its next meeting in Washington, in 1887.

The Paris Faculty of Medicine.—The "Union médicale" states that nominations have been made as follows to the vacant chairs: to the chair of surgical pathology, M. Lannelongue, M. Tillaux, and M. Le Dentu; to the chair of medical chemistry, M. Gautier, M. Boucharlat, and M. Henninger. We learn from the "Gazette hebdomadaire de médecine et de chirurgie" that the successful candidates were M. Lannelongue and M. Gautier.

Poisonous Medicines.—The law making it incumbent on apothecaries to affix special labels to medicines that are particularly dangerous has been pointedly enforced in Philadelphia recently, in a case where a young girl lost her life as the result of taking a number of strychnine pills "for fun," having seen a companion take one of them.

The Death of Dr. Burq was announced in the newspapers last Saturday as having taken place in Paris the day before. The person alluded to is probably the Dr. Burq who has been so well known in connection with metallo-therapeutics, and as having been a persistent advocate of the virtues of copper as a preventive of cholera.

The Virus of Hydrophobia.—The following letter was recently received by Dr. A. S. Heath, of this city, in reply to an inquiry addressed to M. Pasteur:

"8 août.

"August 8th.

"MONSIEUR: En l'absence de M. Pasteur, qui est à Copenhague, je réponds à la lettre que vous lui avez adressée.

"SIR: In the absence of M. Pasteur, who is in Copenhagen, I reply to the letter which you addressed to him.

"Dans un animal mort de la rage il n'y a de virulent que la salive, les glandes salivaires et le système nerveux. Le sang, les muscles, les viscères ne paraissent pas contenir le virus rabique. Je ne connais pas d'exemple d'inoculation de la rage par les manœuvres d'une autopsie.

"In an animal that has died of hydrophobia there is nothing virulent except in the saliva, the salivary glands, and the nervous system. The blood, the muscles, and the viscera do not appear to contain the virus of rabies. I do not know of an instance of inoculation of rabies by the performance of an autopsy.

"Le virus atténué que vous demandez est encore à l'étude. Il n'a été expérimenté jusqu'ici que sur les chiens, et dans l'état actuel de nos connaissances M. Pasteur n'oserait pas en faire, pour le présent, l'essai sur l'homme.

"The attenuated virus that you ask for is still under investigation. Thus far, it has been tried only on dogs, and in the present state of our knowledge M. Pasteur would not dare to make use of it on man.

"Recevez, Monsieur, l'assurance de ma considération la plus distinguée.

"Accept, Sir, the assurance of my highest consideration.

"DR. ROUX,

"DR. ROUX,

"le directeur adjt. au laboratoire de M. Pasteur."

"adjunct director of M. Pasteur's laboratory."

The "Fort Wayne Clinic," we are informed, is the title of a new monthly journal that is to be established at Fort Wayne, Ind.

The American Dermatological Association will hold its eighth annual meeting at Cranston's Hotel, below West Point, on Wednesday, Thursday, and Friday, the 27th, 28th, and 29th inst. The proceedings are expected to include the reading of the following papers: On a Peculiar Scaling Affection of the Glans and Prepuce, by the President, Dr. R. W. Taylor, of New York; On Miliaria and Sudamina, by Dr. A. R. Robinson, of New York; The Neuropathic Theory of Herpes Zoster—is it sustained by Clinical Facts? by Dr. G. H. Rohé, of Baltimore; A Case of Late Cutaneous Syphilis (Acneiform Syphiloderm of the Nose), illustrating the Occasional Necessity of Large Doses of Potassium Iodide, and A Case of Vitiligo involving the Whole Surface, by Dr. H. W. Stellwagon, of Philadelphia; A Case of General Idiopathic Atrophy of the Skin, A Case of Xanthoma Multiplex, and A Case of Sarcoma Cutis (with a supplementary account of a case previously reported), by Dr. W. A. Hardaway, of St. Louis; A Clinical Contribution to the Study of Lupus Erythematosus of the Hand, by Dr. J. N. Hyde, of Chicago; Suggestions respecting the Treatment of Acne and Acne Rosacea in the Male Subject, by Dr. S. Sherwell, of Brooklyn; A Case of Unilateral Chromodrosis, and Cases of Arsenical Dermatitis, by Dr. J. C. White, of Boston; and Dermatitis Herpetiformis, its Relations to Impetigo Herpetiformis, by Dr. L. A. Duhring, of Philadelphia.

The British Medical Association, as we learn from the "Medical Times and Gazette," created a new section at its recent meeting at Belfast—that of Pharmacology and Therapeutics.

Army Intelligence.—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 10, 1884, to August 16, 1884: BARTHOLOMEW, J. H., Captain and Assistant Surgeon. Relieved from

duty at Vancouver Barracks, Washington Territory, and ordered to take station at Portland, Oregon. Par. 1, S. O. 114, Headquarters Department of Colorado, August 1, 1884.

HEIZMANN, C. L., Captain and Assistant Surgeon. Ordered to proceed to Fort Ontario, New York, and report for duty. Par. 3, S. O. 163, Headquarters Department of the East, August 13, 1884.

KANE, JOHN J., Captain and Assistant Surgeon. Granted leave of absence for one month. Par. 1, S. O. 160, Headquarters Department of the East, August 10, 1884.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the Navy for the two weeks ending August 16, 1884:*

SAYRE, J. S., Assistant Surgeon. Ordered to U. S. S. Independence.

BOGERT, E., Medical Inspector. To be Fleet Surgeon, Asiatic Squadron.

BABIN, H. J., Surgeon. Detached from Minnesota and ordered to Marine Rendezvous, New York.

WHITING, R., Passed Assistant Surgeon. Detached from Marine Rendezvous, New York, and ordered to Naval Academy as Member of Examining Board.

COOKE, G. H., Surgeon. Ordered to Naval Academy as Member of Examining Board.

RIXEY, P. M., Passed Assistant Surgeon. Detached from special duty at Washington and ordered to U. S. S. Lancaster.

WOOLVERTON, T., Surgeon. Ordered to U. S. S. Minnesota.

Society Meetings for the Coming Week:

MONDAY, August 25th: Canadian Medical Association (Montreal—first day).

TUESDAY, August 26th: Canadian Medical Association (second day); American Pharmaceutical Association (Milwaukee).

WEDNESDAY, August 27th: British Association for the Advancement of Science (Montreal—first day); Canadian Medical Association (third day); Auburn, N. Y., City Medical Association.

THURSDAY, August 28th: British Association for the Advancement of Science (second day).

FRIDAY, August 29th: British Association for the Advancement of Science (third day).

SATURDAY, August 30th: British Association for the Advancement of Science (fourth day).

OBITUARY NOTES.

Dr. Joseph Janvier Woodward, of the Army.—Although, as was generally known, Surgeon Woodward had been out of health and on sick leave for a number of months past, the news of his death, which took place last Monday, near Philadelphia, will come as a shock to the profession, for he was but little more than fifty years of age at the time of his death, and, in the ordinary course of events, his brilliant career might have been expected to be continued for many years to come.

Surgeon Woodward, major and brevet lieutenant-colonel, was born in Philadelphia in 1832. He pursued his academic course in that city, and was graduated in medicine from the University of Pennsylvania in 1853. He practiced medicine in Philadelphia until he was appointed an assistant surgeon in the army, August 5, 1861. He served with credit and distinction through the war of the rebellion, not only as concerned the performance of his duties to the Government, but also with regard to the advancement of his profession. His observations on camp dysentery and on typho-malarial fever, for instance, were of a nature to throw positive light upon many difficult questions connected with those affections and their management in armies; his original work in microscopy, and more particularly in photo-

micrography, after the termination of the war, was such as to give him a world-wide reputation; and, finally, the excellence of the literary work done by him, in conjunction with the late Surgeon Otis, in preparing the early volumes of the "Medical and Surgical History of the War of the Rebellion" helped not a little to give that work the character which was at once accorded to it wherever medical science is cultivated. Not only the medical corps of the army, but the profession at large, has sustained a serious loss in the death of Dr. Woodward at an age comparatively young.

Reports on the Progress of Medicine.

OPHTHALMOLOGY.

By CHARLES STEDMAN BULL, M. D.

LECTURER ON OPHTHALMOLOGY AND OTOLGY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE; SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY; OPHTHALMIC SURGEON TO ST. MARY'S FREE HOSPITAL FOR CHILDREN AND TO THE NURSERY AND CHILD'S HOSPITAL.

Concussion of the Optic Nerve.—Schweigger ("Arch. f. Augenheilk.," xii, 2, 3) reports three cases of this nature following an injury. The first patient was a boy, aged eight, who three days before had fallen, and in falling had struck his face against the blunt end of an iron instrument. There was a small cutaneous wound in the region of the upper jaw, opposite the first molar tooth, which did not penetrate the buccal cavity, and was nearly healed. He became blind immediately after the accident. There was no external nor ophthalmoscopic evidence of any trouble, but there was not the faintest perception of light. The amaurosis remained for several days, and then the vision began to return, and gradually reached an acuity of $\frac{5}{10}$, with good eccentric vision and good color perception. The second patient was a woman, aged twenty-three, who struck her face a severe blow against a sharp stick, which lacerated the region of the inferior orbital margin. The eye was not injured, but became blind immediately, with no perception of light. The wound soon healed, and the vision gradually improved up to $\frac{6}{10}$, but the field was limited upward, and the lower half of the optic papilla was discolored. The third patient was a physician, who was thrown from his horse and struck on his head. The right eye became at once completely blind. Three months later the vision was $\frac{6}{10}$, and the visual field was intact; but the temporal half of the disc was discolored. In this case there was probably fracture of the base of the skull in the vicinity of the optic foramen.

A Rare Case of Retro-bulbar Optic Neuritis.—Van Milligen (Centrabl. f. prakt. Augenheilk.," Jan., 1884) reports an interesting case of this nature occurring in a man, aged forty, who came to him complaining of a gradually increasing exophthalmus of the right eye of three months' duration, which had been preceded by violent pain in the right cheek and temple. The right eye protruded outward and downward, but there was no interference in its motility, and cornea, iris, and media were normal. There was no sign of anything abnormal in the fundus, and no diminution of vision. The right nasal meatus was narrowed, and the infra-orbital groove very sensitive. The hard palate was normal, but on the left side of the soft palate was a swelling—hard, elastic, and very sensitive. There was no sign of any tumor in the posterior nares or pharynx. The submaxillary glands were quite swollen. Van Milligen made a diagnosis of carcinoma of the maxillary sinus and decided to resect the upper jaw, which was done according to the method of Nélaton. When the superior maxilla was removed, the entire tumor was exposed, and was seen to have

destroyed entirely the posterior wall of the antrum and extended into the retro-pharyngeal cavity. Upward the tumor had caused atrophy of the floor of the orbit, and it had also extended into the sphenomaxillary fossa. After the entire mass had been removed, all the surfaces were cauterized by Paquelin's cautery. The operation was done under carbolic-acid spray and dressed according to Lister's method. The flap healed by first intention, and there was no febrile reaction. The cavity was washed out every two hours with a solution of permanganate of potassium, and then iodoform was blown in. The operation was done on August 19th. On September 6th there was slight œdema of the conjunctiva, and the exophthalmus seemed to have slightly increased. The patient complained of cloudy vision, and there was found a central scotoma, with irregular limitation and a diameter of thirty-five perimeter degrees. $V. = \frac{4}{60}$. The œdema slowly increased, and the motility of the eye became limited. An incision was made through the cicatrix, and gave exit to about four grammes of pus. No change in the scotoma was noticed until September 15th, when a defect appeared in the lower portion of the field. The retinal vessels now presented an engorged appearance, and the temporal half of the disc was pale. The eye was now entirely immovable, and vision reduced to $\frac{2}{60}$. The marked ectropium of the lower lid and the increasing exophthalmus induced van Milligen to do a provisional tarsorrhaphy. When the stitches were removed eight days later, the eye was entirely blind. It was probable that the return of the growth had come from the temporal side of the cavity, from the sphenopalatine fossa, which had produced an inflammation of the orbital tissues. This caused an interstitial neuritis of the ocular end of the optic nerve; and as at this point the macula fibers run peripherally and toward the temporal side, the first symptom was a central scotoma. As the inflammation in the orbit reached the deeper side, part of the optic nerve lying farther back became involved, and with it naturally the optic-nerve fibers destined for the periphery of the retina; and thus was explained the diminution in the acuity of peripheral vision. Van Milligen explains the circumstance that the upper half only of the retina became non-sensitive by assuming that the orbital inflammation had a circumscribed character, and that only certain parts of the trunk of the optic nerve were attacked by the interstitial proliferation.

Bilateral Dermoid Tumor of the Sclero-corneal Margin.—Wicherkievicz (*Ibid.*) reports a case of this nature in a young girl aged eleven. In the right eye, in the infero-temporal quadrant, was a yellowish-white, elongated swelling lying partly on the cornea and partly on the sclera, which reached almost to the lower *cul-de-sac*. This growth measured ten millimetres in length, four millimetres in width, and two millimetres in height. It was slightly movable over the sclera, but was firmly united to the cornea, and the overlying conjunctiva was adherent to it and was highly vascularized. A similar, though much larger tumor, occupied a perfectly symmetrical place in the left eye, reaching quite to the *cul-de-sac*, and it covered about two thirds of the infero-temporal quadrant of the cornea. On the tragus of the left ear was a similar tumor like a small cock's comb, and on the right auricle was another growth, somewhat smaller. The conjunctiva overlying the tumor in the right eye was divided at the scleral periphery and the tumor grasped with a pair of toothed forceps, and it was then carefully dissected free from its attachments to the cornea and sclera. The conjunctiva was then dissected up on all sides and brought together with sutures. The same operation was done on the left eye. Both wounds healed very readily without any suppuration, and there has been no return of the growths.

The Visual Act in Strabismus Convergens Concomitans.

—Ulrich ("Kl. Mon. für Augenheilk.," Feb., 1884), in investi-

gating this subject, has divided his cases into groups or classes as follows: 1. Those patients who complained of spontaneous diplopia and antagonism or confusion of the visual fields dependent thereon he has grouped together under the name of physiological diplopia and confusion of the visual field, since the visual act shows the same relation as in sudden interruption of physiological vision. These cases were six in number, and in all of them there was periodic convergent squint; they were to be regarded as recent cases both as regards the duration and the periodicity of the squint. 2. A second group of cases consisted of those who complained of more or less frequent diplopia, but there was no antagonism of the visual fields. This group he calls *central exclusion*, and it consisted of eleven cases: three of periodic squint, one of alternating squint, and seven of uniocular squint. 3. In the third group of cases there was no complaint of either antagonism of the visual fields or of spontaneous diplopia, though the latter could be produced by holding prisms in any direction before the squinting eye. This group he calls by the name of *centro-paracentral exclusion*; it numbered nine cases: one of periodic convergent squint, two of alternating squint, and six of uniocular squint. 4. In a fourth group there was neither antagonism of the visual fields nor spontaneous diplopia, and the latter could only be produced by a prism with the refracting angle placed upward or downward before the squinting eye. As in these cases a horizontal strip of the retina of the squinting eye, of varying width, in which the macula lies, is excluded, he calls this group by the name of *horizontal exclusion*. In this group there were six cases, all of uniocular strabismus. 5. The fifth group was one of total exclusion. The entire retina of the squinting eye was concerned in the visual act only so far as it furnished a certain amount of clearness to the retinal perception of the fixing eye. Diplopia could not be produced by any method. In this class were grouped together two kinds of diametrically opposed cases, with reference to the visual acuity of the squinting eye. Total exclusion was present, almost without exception, in all cases of convergent squint in which the squinting eye was so amblyopic that fingers could only be counted eccentrically at a few feet. There were twenty-one cases of total exclusion without this high degree of amblyopia, viz.: four of periodic strabismus convergens, eight of alternating strabismus convergens, and nine of uniocular strabismus convergens. 6. The sixth class consisted of six cases of unilateral exclusion. 7. The seventh group consisted of two cases of periodic squint marked by exclusion, together with transient binocular vision. Ulrich holds that it is an incontestable fact that in children with strabismus convergens a previous binocular visual act has been present, even if the perception of the three dimensions of space has not yet been developed, and he gives his reasons for this belief as follows: 1. In a certain number of individuals in whom strabismus appeared at a not very early age, the previous presence of a binocular visual act can be directly inferred from the character of the visual disturbance. 2. In individuals whose age does not admit of an examination on this point it is still possible to demonstrate a faulty projection of the squinting eye. 3. In many adult individuals who suffer from alternating squint, with preference of one eye for fixation, antagonism of the visual fields may be demonstrated when they endeavor to fix with the usually squinting eye. 4. In periodic squint there is present the binocular visual act, together with exclusion. The strabismus convergens sometimes met with in small children during the course of a superficial keratitis Ulrich explains as follows: The photophobia accompanying the keratitis first causes blepharospasm in the affected eye, and, while the disturbance of diplopia and confusion of the visual fields are thus avoided, the squint may quietly develop.

Periodic Exophthalmus on Forward Inclination of the

Head.—Magnus (*Ibid.*) reports a case of this kind in a boy, aged thirteen, which had appeared immediately after birth. When erect, the eyes were normal in appearance and motility, and there was no difference in size between the two eyes. Both had a manifest hypermetropia of $\frac{3}{8}$ with normal vision. The inter-palpebral fissures were equal and normal. At the inner angle of the left eye was a blood-red, small, lobulated tumor, just beneath the caruncle. On lifting the upper lid, this tumor was seen to extend as a lobulated, blue-red structure as far as the superior *cul-de-sac*. On the nasal side it was not possible to mark out any limit to the tumor, but toward the temple the tumor did not extend beyond the middle of the lid. It seemed to come from the inner half of the orbit, and pushed the conjunctiva before it. The cutaneous surface of the lid was normal, but on the inner half of the free margin of the lid there was a blue discoloration. Similar blue spots existed on various parts of the patient's face. After the boy had sat with his head bowed forward for five minutes, the left eye became markedly dislocated outward and downward, and protruded far out of the orbit, but its motility was not impeded, and there was no diplopia. No examination could now be made of the orbital margin, owing to the presence of a firm, elastic tumor. After the boy had resumed the upright position for about one minute the eye returned to its normal position again. All the bluish spots upon the face became more or less prominent in the bowed position of the head. The diagnosis was made of varicose dilations of the veins in the left half of the face and head, especially upon the inner wall or face of the orbit, of congenital character.

The Position of the Visual Center in Man.—Nieden ("Bericht der ophthal. Gesellschaft," Beilageheft der "Kl. Mon. für Augenheilk.," 1883) reports a case of pure, unioocular, temporal hemianopsia of the right eye following an injury to the visual center of the left hemisphere. It occurred in a female, aged twenty-one, who displayed grave cerebral symptoms and right hemiplegia after a severe fall on the occiput. The absence of all pathological ophthalmoscopic symptoms, as well as of any visual disturbance of central or peripheral vision, seemed to point, in connection with other symptoms, to the existence of a subdural abscess in the region of the injury. This spot, which showed a transverse fissure, was trephined, and in the operation the dura and cortex were injured. No abscess was found, but there was inflammation of the dura. The general symptoms rapidly improved after the operation, but there appeared a defect in the temporal half of the visual field of the right eye, which, however, did not involve the immediate region of the macula. On the left side there was a general concentric limitation, which remained permanent, after all other symptoms had disappeared, and was accompanied at a later date by a defect in the median half of the visual field of the left eye in consequence of the cicatricial process in the wound of the cortex.

Astigmatometry and a new Astigmometer.—Zehender (*Ibid.*) here describes a new astigmometer, consisting of two pasteboard tubes, one of which fitted into the other and could be revolved around its long axis. At the objective ends of both tubes were two threads running diametrically, and arranged parallel to one another, so that, when the tubes were caused to slide the one within the other and rotated toward each other, the two systems of threads stood perpendicularly to each other and formed a rectangular cross. The apparatus rotates in a ring and is fastened to a stand. When the threads are so placed that they cross each other at right angles, and a non-astigmatic eye looks into the tube, it will see the cross sharply defined in all its parts. The eye which does not see both arms of the cross with equal distinctness is astigmatic.

The inner tube is then to be rotated until one of the two systems of threads appears sharply defined; the other system will then have its maximum indistinctness. The direction of the two chief meridians is then determined, and can be read off on the ring or on the rotation of the tube around the fixed ring. The particular spherical glass must then be found which makes the indistinct thread perfectly clear and defined, and this determines the degree of the a-tigmatism. By this instrument the direction of the chief meridians is determined by the rotation of the object of fixation before the eye of the patient, and cylindrical glasses are dispensed with. As an improved modification of the instrument, Zehender has inserted in front of the apparatus a spherical glass, which rotates round its transverse axis. By inserting a cylindrical glass in the apparatus and holding any spherical glass of the opposite refracting power in front of it, it is possible to determine a position of rotation, exactly defined by an index, in which the effect of the cylindrical glass is entirely neutralized. If stronger glasses are employed, it is possible to determine accurately to within one degree the position which any spherical glass must assume to correct the effect of any cylindrical glass.

Inflammation of the Capsule of Tenon.—Berger (*Ibid.*) reports the results of the examination of a phthisical eyeball and orbital contents removed from the body of a retin. In removing the eye from the orbit, a fibrous, coagulable mass was found inside the capsule of Tenon. Under the microscope this was found to consist of fresh (embryonic) connective tissue, with some endothelium from the capsule of Tenon. The capsule itself was thickened, loosened, and infiltrated with round cells. The neoplastic tissue rendered the removal of the eye from the capsule very difficult. It began at a point 3 or 4 mm. from the sclero-corneal margin, covered the entire surface of the eyeball, and extended backward into the supra-vaginal lymphatic space of the optic nerve. The cornea was shrunken; the anterior chamber was very small. The lens was absent. The ciliary body was separated from the choroid. The organized connective-tissue exudation which filled the supra-choroidal lymphatic space was in places 4 mm. thick. The degenerated iris was firmly united with the cyclitic membranes behind it, and indirectly with the cicatricial connective tissue. The retina was detached. In the posterior part of the eyeball, in the region of the optic nerve, the choroid was ossified. In the inter-vaginal lymphatic space of the optic nerve was a mass of neoplastic connective tissue.

Jequiry Ophthalmia.—Von Hippel (*Ibid.*) has a lengthy article upon this interesting subject. He began his investigations by endeavoring to determine whether there existed any demonstrable difference in effect between preparations made of the hulled beans and those made from unhulled beans, which question he answers in the negative. He then determined the minimum dose which would produce the characteristic ophthalmia in the normal conjunctiva of a rabbit and the granular conjunctiva of man, and also investigated the question whether the intensity of the inflammation was proportional to the degree of concentration of the maceration, and this question was answered decidedly in the negative. Von Hippel does not think that the temperature of the room in which the maceration is made has any influence upon its action. He agrees with Sattler, however, that after the fifth week the action of the jequiry is much slighter, and the inflammation caused by it is much milder, and after two months have elapsed it produces no effect whatever. But, when the beans are macerated in carbolized or salicylated solutions of definite concentration, the solution retains its activity for months, whether the vessel containing it is closed or open. The characteristic ophthalmia may always be produced, no matter how the maceration-solution is employed. The dos-

ing or regulation of the inflammation, according to the dictum of Wecker, is only possible within very narrow limits. Von Hippel does not regard the jequirity ophthalmia as absolutely without danger. He has used the remedy only in the various forms and stages of ophthalmia, and he has found it perfectly valueless in fresh granulations with marked conjunctival hyperæmia. But he has found it useful in chronic trachoma, with and without pannus, as well as in cases of shrunken conjunctiva and dense pannus. He dissents from Sattler's view, that jequirity ophthalmia is a new infection-disease, on the following grounds: 1. Because there is no analogy for the development of an infection-disease without any stage of incubation. 2. Because he did not succeed in a single instance in producing in a healthy eye a jequirity ophthalmia by the introduction of the secretion or of membranous shreds from an inflamed eye. 3. Because we have no right to regard the bacillus of Sattler as one peculiar to the jequirity-maceration, as he has found it but rarely either in the secretion or in the membranes. Furthermore, in the conjunctiva and infiltrated lid he constantly met with small, round micrococci in large numbers, which were of a very different shape from this bacillus and could not be mistaken for it.

New Inventions, etc.

THE EXHIBITION OF INSTRUMENTS AT THE RECENT MEETING OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION.

DR. DOUGLAS presented two powder applicators, invented by himself.

DR. JARVIS presented a laryngeal snare.

DR. MACKENZIE presented a self-retaining nasal speculum, and also announced a proposed method of illumination of the nasal cavities.

DR. SEILER said, with regard to illumination of the nasal cavities by the Edison incandescent light, that he had tried it, burned himself, and would not think of trying to use it on a patient.

DR. INGALS presented an instrument designed for carrying the wire loop of a snare up behind the palate in removing nasopharyngeal growths. The instrument was shaped much like an ordinary post-nasal forceps, but on the upper surface of the blades were slides, which fixed the wire in notches at the extremity of the blades, while they were being introduced and opened out over the growth, and allowed the release of the wire after it had been fixed in proper position, the snare attached, and the loop partially tightened. He had found the instrument peculiarly serviceable in removing large nasopharyngeal tumors.

In the case for which he had the instrument constructed he had worked patiently for about three hours to apply first the steel and afterward the platinum wire, and had been obliged to give it up; but he had succeeded in about two minutes after he procured the instrument.

DR. SAJOUS presented three new instruments, and said: The tonsillotome herein described is somewhat smaller than Mathieu's, and the general conformation of the blades is preserved; but, instead of being furnished with a side-shaft for the fork, the spear which takes the place of the latter is attached to the main shaft by means of a thumb-screw. The lower edge of the spear is straight throughout one half of its length, then oblique, and rests in a grooved guide-screw which passes through a slot in the shaft and is fastened to the blade. When in action, it

perforates the tonsil and draws it out without causing the jar occasioned by the sliding-screw of Mathieu's. A spear is made to replace the fork, to avoid the difficulty generally experienced in separating the cut-piece from the latter; it holds it sufficiently to prevent its dropping into the throat, and can be easily withdrawn when partly in the tonsil, should a calcareous concretion be met with.

The thumb-ring is screwed on the main shaft, bringing it in a direct line with the finger-rings. By this arrangement the equilibrium of the instrument is maintained during the operation, whether operating on the right or the left tonsil.

The main shaft is not continuous with the blade-rings, as in Mathieu's; they are separate, and the latter are furnished with rods which fit and move easily in longitudinal grooves extending an inch and a half along the side of the shaft. By this arrangement any size of blade or ring can be adjusted to the shaft, the three sizes presented having served the inventor in twenty-seven operations, and in each case the rings fitting tightly around the tonsil, a desideratum for a neat operation and an even surface.

FIG. 1.

FIG. 2.

FIG. 3.

As shown in Fig. 1, the instrument is ready for the operation, the manipulation being the same as with Mathieu's. When the thumb-ring and finger-rings are approximated by the operator, the spear enters the tonsil until the beveled end of the main shaft slips under a small spring situated near the grooved guide-screw, from which a pin reaching down to the blade protrudes. The spring being raised, the pin is lifted out of the hole in the blade, setting it free, and the knife, following the motion of the fingers, cuts through the tonsil.

One of the annoying features of tonsillotomes in general is the difficulty attending their cleansing. Especially is this the case in Mathieu's, a screw-driver being necessary to disengage the blade from the shaft and blade-rings. In the new instrument, traction on the blade-rings with the left hand will cause them to slip half way out of the shaft until a pin projecting from the lower surface of one of them becomes engaged in a

FIG. 4.

"safety" groove near the end of the knife. The finger-rings are now pushed away from the thumb-ring, thus causing the blade to occupy the position it held before the operation. The

rings being thus allowed to slip farther out, they become disengaged from the shaft, leaving the blade exposed.

The tip of the spear is now turned aside by lifting it out of the grooved guide-screw and the piece of tonsil taken off. Each exposed part can be cleansed thoroughly and readjusted in a few seconds. If necessary, the whole instrument can be taken apart by merely unscrewing the thumb-ring.

Dr. SARGENT then showed a septum forceps, and said: This forceps, in general shape and size, is like Adams's, but the blades are separable, a turn of the thumb-screw, like that in an obstetrical forceps, causing them to fall apart. This enables the operator to introduce one after the other into the nostrils, and to lock them when in proper position. Instead of forming a part of one of the blades, the knife or punch is independent and can be adjusted to it by passing the shouldered pin with which it is furnished, as shown in Fig. 5, through a hole near the end of the instrument. This enables the operator to use any shape of knife he may think adaptable to his case.

FIG. 5.

The knives can be turned in any direction, according to the longitudinal axis of the deviation, and but one forceps becomes necessary for punching and straightening, the knife being easily taken off.

FIG. 6.

The knives and punches shown in Fig. 6 are a small oval punch to perforate the septum, a Steel's punch, an elliptical punch with diverging blades to cut off sharp bends of the cartilage and reduce its elasticity when being straightened, and two small blades—one curved and one straight—with which any shape of figure or cut can be made in the septum. For instance, the shape of saw-teeth in a redundant septum can be made by alternately raising and lowering the handle of the forceps. The sharp ends will overlap and give a result which could not be obtained with a small punch.

Dr. SARGENT also showed a uvulatomer and said: The uvulatomer consists of a pair of strong scissors with the handles slightly bent. Its lower surface is armed with a pair of toothed claws, the stem of which is connected with the handles by means of two little arms. These being attached loosely, the claws have free longitudinal motion, guided by the pivot-screw of the scissors, and kept in position by a cap which not only serves that purpose, but also approximates the toothed edges of the claws by the resistance it offers to their outer edge.

The instrument being held with the palm of the hand directed toward the operator—that is to say, with the thumb and finger passed through the rings from below upward (the bend being just sufficient to prevent them from interfering with the line of vision)—it is introduced closed into the mouth. As soon as the point has reached the uvula, the rings are separated, and the organ hangs between the teeth of the claws. The rings being now approximated, the claws close on the uvula before

the blades touch it, hold it fast, and bring it forward by bending it at its base. The scissors cutting it in that position, the cut surface is oblique and posterior. When food is swallowed,

FIG. 7.

the horizontal surface obtained with other instruments is exposed to the bolus, and scraped and kept sore by it for several days. With the posterior oblique surface obtained with this instrument, the bolus only touches the anterior surface of the stump, the cut surface resting against the pharynx. The healing process is more rapid, and a better stump is obtained. Slipping of the uvula between the blades is impossible, and the cut is always complete.

Dr. DELAVAN called the attention of the association to a new method for the alimentation of patients suffering from dysphagia, and presented an instrument designed to facilitate the feeding process.

The essential principles of the method were (1) the use of a tube of small caliber instead of the ordinary stomach-tube, and (2) the introduction of this tube, not into the stomach, but simply below the pharyngeal constrictors, or beyond the seat of the difficulty. The instrument consisted of an ordinary conical-

FIG. 8.

bottomed soda-water bottle, furnished with an India-rubber stopper. In the latter were two perforations, through each of which was passed a glass tube, bent just outside the cork at a right angle. One of these was short, the other long enough to reach the bottom of the bottle. To the short one was attached a Davidson air-compressor. To the other a flexible rubber tube, connected with an English flexible woven catheter, in size from No. 8 to No. 18. The catheter having been introduced into the oesophagus, the fluid in the receiver was forced through the tube by compressing the air in the receiver by means of the rubber bulb.

Dr. DONALDSON remarked that he had found the most convenient instrument for introducing food into the stomach to be the fountain syringe.

Dr. SEILER and others offered certain theoretical objections

to the tonsillotome and the uvulotome presented by Dr. Sajous, but Dr. Sajous replied that, practically, the objections did not hold except the one with regard to the curve of the handles of the uvulotome, and that would be corrected. He had employed the instruments in a number of cases with entirely satisfactory results.

Dr. COHEN said, with regard to deformity of the nasal septum, that he had not found instrumental treatment of much value. Lately he had been in the habit of dilating the alæ, putting in a nasal plug of cotton, and leaving it there a day, during which time it formed a mold of the cavity. He then had a mechanic form a wooden plug from this, which the patient wore an hour or two every day for some time. The results had been very satisfactory. In two cases, however, the wooden plug had given rise to considerable ulceration of the septum, but, by taking the plug out and introducing cotton, the ulceration had disappeared.

Miscellany.

THERAPEUTICAL NOTES.

The Action of Convallaria on the Heart.—From a number of elaborate experiments on terrapins and frogs, Dr. H. Y. Beyer, of the navy ("Proceedings of the Naval Medical Society," ii, 1, 1884), concludes: 1. That convallaria increases the rate of the heart's action. 2. That the work which the organ has to do is slightly increased. 3. That the drug raises the intra-cardiac and aortic pressure. 4. That both auricles and ventricles are arrested in systole when medium doses are used. 5. That large doses arrest the heart at once. 6. That the results are most probably due to direct action on the muscular substance of the heart. 7. That the drug has a decided cumulative action, acts much slower than digitalis, and is much more persistent after the heart is once under its influence. He adds that the whitish, shrunken, and puckered appearance which the heart presents when very much under the influence of convallaria, the slow appearance of this phenomenon, and its persistence, all speak in favor of the view that the muscular substance of the heart is much interfered with. So far as his experiments go, the author thinks that they warrant the conclusion that convallaria is contra-indicated in advanced cases of cardiac disease in which the muscular structure of the heart has undergone degeneration. Convallamarin should be used in preference to any other preparation of the drug, and, on account of its cumulative action, not more than one full medicinal dose should be given in a day.

Hypodermic Injections of Iodoform in Syphilis.—The "Bulletin général de thérapeutique" gives a summary of an article recently published in a German journal by Dr. E. Thomann, of Graz, who has treated a number of cases of severe syphilis with subcutaneous injections of iodoform, and has always observed an evident amelioration after ten or twelve injections. He uses a mixture of six parts of iodoform and twenty parts of glycerin, and injects from 30 to 75 centigrammes of the mixture at a time. The injections have never caused abscesses, but only a little swelling and pain at the site of the puncture. Iodine may be detected in the urine at the end of two hours, but no odor of iodoform can be perceived in any of the excretions. A solution of iodoform in olive-oil was tried also, but it was found more irritating than that in glycerin.

The Treatment of Conjunctivitis.—The treatment of this affection, whether simple, catarrhal, contagious, the result of a physical or chemical irritant, or occurring as the sequel of an infectious disease, as carried out at M. Abadie's clinic, has been furnished to the "Progrès médical" by M. Darier, the *chef de clinique*.

At the outset, when there is only a conjunctival hyperæmia, with little or no secretion, the eyes are to be washed five or six times a day with a solution of boric acid in distilled water—one part to thirty. By

reason of its antiseptic and slightly astringent properties, this solution often prevents the development of grave forms of the disease or of those which are apt to become chronic; in the course of a few days the conjunctiva will be found to have resumed its normal aspect, and the symptoms to have disappeared rapidly.

In the graver cases, where the conjunctiva is very red and turgescient, and the sclerotic can scarcely be seen through the gorged vascular network, while the lids are swollen, red, and stuck together in the morning with a muco-purulent secretion, cauterization should be practiced with a solution of nitrate of silver in distilled water—one to two hundred. The manner in which these cauterizations are performed is of the greatest importance. In the hands of others than specialists the solid stick, pure or mitigated, is not very satisfactory; instillations of collyria are not much to be trusted to; so the invariable custom is to prescribe the use of titrated solutions, directing that the whole conjunctival surface be carefully brushed with them. To do this, it is necessary to make the patient look down, so as to cause the whole upper lid to stand well out from the globe; the lid is then to be seized by its ciliary border and suddenly turned upward, slight pressure being made at the same moment with the handle of the brush on the upper edge of the tarsal cartilage, in order to invert it. In this way, the patient looking down all the time, the upper conjunctival *cul-de-sac* may be cauterized at every point; to touch the lower sac it is sufficient to make the patient look up while the ciliary border is pressed down, which will evert the lid completely.

The application is to be made more or less lightly, according to the intensity of the inflammation. In cases of some severity the brush wet with the solution should be applied until the conjunctiva assumes a rosy-white appearance; the eye is then to be bathed freely with pure water, the solution of chloride of sodium being altogether useless; and that is all. For the first two or three days the cauterizations should be practiced every twenty-four hours, and then every forty-eight hours. In the intervals the eyes should be bathed frequently with the solution of boric acid.

When the conjunctivitis has become chronic, it is most commonly accompanied by a moderate marginal blepharitis; it will then be well to use compresses wet with a mixture of twenty drops of liquor plumbi subacetatis and half a tumblerful of water, or a solution of sulphate of zinc in distilled water—one to three hundred—the compresses being held upon the half-open lids for a few minutes.

Hydrastis Canadensis.—The "Lancet" states (without giving the source of its information) that M. Schatz has employed a fluid extract of this drug in fifty cases of uterine hemorrhage due to various causes. The results have been very satisfactory in about two thirds of the cases. Metrorrhagia due to fibroid tumors, post-puerperal metrorrhagia, and menorrhagia about the time of puberty, were the affections most readily relieved. The fluid extract was given in doses of twenty drops three times a day. The treatment was begun a week or more before the commencement of the period of menstruation. Under its influence the duration of the catamenia was diminished and the blood discharged was lessened, and in some cases there was actual suppression. M. Félner has investigated the physiological action of the fluid extract of *Hydrastis canadensis* on dogs, and attention was strictly confined to the vessels, heart, small intestine, and uterus. In large doses (two to five grains [*sic*]) the fluid extract injected directly into the veins momentarily raises the intra-vascular pressure; but this first phase is soon followed by another in which the blood-pressure sinks permanently below the normal level, and death may ensue. When doses of 1·2 to 1 gramme [*sic*] are employed in the form of hypodermic injections, the lowering of the blood-pressure is less pronounced and takes longer to appear, but it is still persistent. At the same time the elevation of the intra-vascular pressure lasts a longer time. In still feeble doses the initial effect is, on the contrary, a diminution of the blood-pressure of very short duration; and the secondary effect is an elevation of the blood-pressure, which persists indefinitely. When a number of minute doses are injected in succession, the final result is the same as with a single dose. The subcutaneous injection of a strong dose (two grammes) determines, first, a transient decrease in the blood-pressure; this then passes away for a brief period, to be again followed by a fresh lowering, not in a continuous fashion, but by a series of well-marked oscillations. The results are the same when the drug is given by the rectum or stomach.

Previous section of the splanchnic nerves does not appreciably modify the effects produced by intra-venous injection of small or large doses of the fluid extract. The same fact holds good of compression of the abdominal aorta. Section of the cervical portion of the spinal cord does not stop the action of the drug in lowering blood-pressure. Strychnine can to a certain extent undo the effects of hydrastis on the blood-pressure. By direct inspection the small intestines are observed to be injected during the period of lowered blood-pressure, and to be exsanguinated when the blood-pressure is raised again. Hydrastis is believed thus to have a powerful effect on the vaso-motor apparatus, due to an excitation of the cerebral centers. During the first stage of the action of the drug the pulse is slowed. This delay may go on to complete arrest of the heart's action; it appears to be due to excitation of the central end of the vagus, because it does not occur when the pneumogastric nerves are divided. After the injection of large doses the slowing of the pulse with syncope is met with during the second stage, when the blood-pressure is diminished. In this stage previous division of the vagi exercises no influence on the frequency of the heart's action. All injections give rise to contraction of the womb, both of its body and of its horns; the maximum effect is produced a short time after the injection; later on, however, manifest contractions do take place, chiefly of the cornua. The uterine contractions are synchronous with those of the blood-vessels.

The Quarantine Defenses of New York.—The "Sanitary Engineer" publishes the following summary: A maritime quarantine for the protection of the public health of New York was established as early as the year 1758, but it is under the General Quarantine Act of April 29, 1863, and its subsequent amendments, that the present quarantine is administered. The quarantine establishment consists (1st) of an outer boarding-station—a ship at anchor in the lower bay, five and a half miles from the Narrows and twelve and a half miles from the Battery, or the extreme lower end of Manhattan Island; (2d) an outer quarantine roadstead in the lower bay about one mile inside the outer boarding-station; (3d) an artificial island (Swinburn's Hospital Island) containing ten detached hospital buildings, two and a quarter miles outside the Narrows; (4th) Hoffman Island, one mile nearer the Narrows, and an "observation station" containing buildings for the accommodation and observation of 1,600 persons; (5th) the upper quarantine roadstead, just inside the Narrows, and the regular boarding-station, the year round, for all vessels, and where the affairs of quarantine are administered, including residences for officers and men, about one mile south of Clifton Landing; and (6th) Robbins's Reef Anchorage, where infected vessels are discharged and cleansed.

The affairs of quarantine are administered by a quarantine commission of three members and the Health Officer of the Port, appointed by the Governor and confirmed by the Senate, and the Mayors of New York city and Brooklyn are *ex-officio* members of the commission.

The Health Officer, under the law, must be a doctor of medicine in good standing, with ten years' experience in the practice of his profession, and be practically familiar with the diseases subject to quarantine. His duties are the general superintendence and control of quarantine, the care and treatment of the sick, and the carrying out of all the provisions of the law and regulations. He has power to administer oaths and take affidavits. He can at all times call upon the metropolitan police to the number of ten to aid him in an emergency to enforce the duties conferred upon him, or to direct in writing any constable, or even citizen, to pursue and apprehend any person violating quarantine law or regulations, and can detain such persons ten days. A person obstructing the Health Officer is guilty of a misdemeanor punishable by a fine not less than one hundred nor more than five hundred dollars, or by imprisonment from three to six months. He has power to *appoint or dismiss at pleasure* all employees under himself, and in conjunction with the Quarantine Commissioners, to license lightermen, steredores, and as many others as may be found necessary for the care and purification of vessels, merchandise, baggage, etc. The law provides for two deputy health officers, whom he appoints and whom he is directly responsible for, and who are authorized to perform all the duties in his absence. The Health Officer, his deputies and assistants, take an oath of office. His prescribed duties are:

To board every vessel subject to quarantine or visitation by him, as soon as practicable after her arrival; to inquire as to the health of all persons on board, and the condition of the vessel and cargo, by inspection of the bill of health, manifest, log-book, or otherwise; to examine, on oath, as many and such persons on board as he may judge expedient to enable him to determine the period of quarantine and the regulations to which such vessel and her cargo shall be made subject, and to report the facts and his conclusions, and especially to report the number of persons sick and the nature of the disease with which they are afflicted, to the Quarantine Commissioners.

To exercise dispatch in the disposal of persons arriving in infected vessels; to have the bodies of persons who have died of malignant diseases on board of infected vessels arriving, and such as shall have died in the hospital, interred in the quarantine burying-ground; and to proceed, without delay, in the purification of vessels, merchandise, baggage, dunnage, and other articles in quarantine; and, whenever he shall judge the same free from infection, to permit the removal thereof. No vessel or cargo, however, that has been in quarantine shall be permitted to proceed to New York or Brooklyn without the approval of the Mayor or Board of Health of those cities respectively.

To secure the effects of the deceased persons in quarantine from waste and embezzlement, and make a true inventory thereof, and, when the rightful claimants of such effects do not appear within three months, to deliver the same, with such inventory, to the Public Administrator, unless the said property be of such description as ought not to be removed or may be destroyed under the provisions of the act.

To keep the Boards of Health of New York and Brooklyn at all times informed of the number of vessels in quarantine, of the number of persons sick in the floating hospital, and of the diseases with which they are afflicted.

To receive any vessel or merchandise sent to him by the health authorities of New York or Brooklyn, dangerous to the public health.

To receive into the floating hospital any case of yellow fever that shall have been contracted in quarantine establishment or elsewhere.

To have all vessels, warehouses, and merchandise in quarantine designated by a yellow flag; and to prohibit communication with, or passage within range of, such vessels and places, except under such restrictions as he may designate as being compatible with safety.

Whenever the Health Officer, in the performance of his duties and in the execution of the powers imposed and conferred upon him by law, or by any regulation or ordinance made in pursuance of any statute of this State, shall order or direct the master, owner, or consignee of any vessel subject to quarantine to do any act or thing, or comply with any regulation, relative to said vessel, or to any person or thing on board thereof, and said master, owner, or consignee shall neglect or refuse to comply with such order or direction, the said Health Officer shall have power to employ such persons and assistance as may be necessary to carry out and enforce such order and direction, and the persons so employed shall have a lien on such vessel, her tackle, apparel, and furniture, for their services and expenses.

Vessels arriving at the port of New York are to be subject to quarantine as follows: All vessels from infected ports, or which shall have arrived at any such place, and proceeded thence to New York, or on board of which during the voyage any case of such disease shall have occurred, or vessels from any place (including islands) in Asia, Africa, or the Mediterranean, or from any of the West Indies, Bahama, Bermuda, or Western Islands, or from any place in America, in the ordinary passage from which they pass south of Cape Henlopen.

What Diseases are Quarantinable.—The only diseases against which quarantine applies are: Yellow fever, cholera, typhus or ship fever, and small-pox, or any disease not now known, of a contagious, infectious, or pestilential nature.

Merchandise subject to quarantine are: 1. Clothing, personal baggage, dunnage, rags, paper-rags, hides, skins, feathers, hair, and all other remains of animals, cotton-hemp and woolsens, on which quarantine is obligatory. 2. Sugars, silks, linen, and cattle, on which it is optional.

The law provides that the Commissioners of Emigration shall receive into their hospitals all alien passengers arriving at the port of New York

who shall be affected with any contagious or infectious disease other than yellow fever. For this reason small-pox patients are sent to Blackwell's Island, and typhus or ship-fever patients to Ward's Island; the cholera or yellow-fever patients to be taken care of by the Commissioners of Quarantine, at their hospitals on Swinburn's Island.

Of the duties of pilots in relation to vessels subject to quarantine, the law requires that the pilot must use his utmost endeavors to hail every vessel he shall discover entering the port, and to interrogate the master in reference to all matters necessary to enable him to determine whether such vessel is subject to quarantine, and he has the power to order the master to proceed to the anchorage in the lower bay if quarantinable diseases are found on board.

The routine of quarantine, in brief, is: Vessels from infected ports are brought by the pilot to the lower boarding-station. The deputy Health Officer there examines her, transferring the sick (if any) to Swinburn's Island, and those that have been exposed to Hoffman Island until after the period of incubation of the disease is passed, where their clothes and persons are washed, and what will not wash fumigated. Vessels from England, or from presumably healthy ports, pass to the upper boarding-station, where they are examined and allowed to pass, or returned to the lower grounds, as the case demands.

If, in the judgment of the Health Officer, the vessel requires it, he may order the following sanitary measures: Baths and other bodily care for the person; washing or other disinfecting means for clothing; displacement of merchandise on board, or complete breaking out of the vessel; subjection to high steam, incineration, or submersion at a distance below the surface of the water, for infected articles; the destruction of tainted or spoiled food or beverages; the complete ejection of water; thorough cleansing of the hold, and the disinfection of the well. In short, the complete purification of the vessel in all her parts by the use of steam, fumigation, force-pumps, rubbing, or scraping, and saturation with a solution of sulphate of iron, and finally sending to quarantine anchorage until disinfection be perfected. Whenever these operations are necessary, they shall always be executed before admission to pratique.

Persons with insufficient evidence of vaccination are not allowed to proceed until they are vaccinated.

The American Association for the Advancement of Science.—The permanent secretary, Mr. F. W. Putnam, of Salem, Mass., announces that, in order to allow of an interchange of courtesies between the British and American associations, and enable the members of the two to attend both meetings, the meeting of the latter this year will take place at a later date than usual. The British Association will meet at Montreal on Wednesday, August 27th, and the meeting will close on the following Tuesday. On Thursday, the 4th of September, the American Association will meet at Philadelphia.

The Council of the British Association has invited the fellows of the American Association to join in the meeting at Montreal on the footing of honorary members, and the American Association and the Local Committee of Philadelphia have invited the members of the British Association, with their near relatives who may be with them, to take part in the Philadelphia meeting. Invitations have been sent to the leading scientific societies abroad, inviting them to send delegates to the Philadelphia meeting. The probabilities, therefore, are that the Philadelphia meeting will be largely international in its character, and it is likely that steps will be taken to form an International Scientific Association. At the same time with the Association meeting the International Electrical Exhibition will be taking place in Philadelphia, and probably at the close of the week an Electrical Congress will be held. Other bodies will also be in session during the week, among them the Pennsylvania State Agricultural Society and the American Institute of Mining Engineers.

The Local Committee are actively engaged in perfecting their arrangements for the accommodation of the large number of persons which the unusual circumstances will call to Philadelphia, and, while the contemplated arrangements provide for two thousand members of the Association, it is earnestly requested by the committee that they be notified as early as possible of the intention of members and their families to be present. All members who intend to be at Philadelphia

should, therefore, notify the Local Secretaries at an early day, and at the same time give their addresses where the Local Circular will reach them, if they are to be absent from their permanent homes during the summer. Definite information in relation to lodgings and transportation will be given in the Local Circular, with much other important information. The hotels have agreed to reduce their rates to the members of the Association, and lodgings will be available at from one to four dollars a day, and private hospitality will also be offered, particularly to the foreign guests.

A series of receptions will be offered the Association and its guests, including one at the Academy of Music after the President's Address, a reception at the Academy of Fine Arts, a Garden Party at Haverford College, and a Microscopical Exhibition at the Academy of Natural Sciences. The Botanical Section of the Academy of Natural Sciences will hold at the Academy a special meeting for botanists. There will also be visits to the International Electrical Exhibition, the Zoological Gardens, Fairmount Park, Independence Hall, and other places of interest, and the various institutions in the city will welcome the Association to their halls. During the meeting free excursions will be offered to the sea-shore, the anthracite coal regions, and other places of interest, and possibly limited excursions to more distant points, after the meeting. Special botanical and geological excursions will also be given.

The Local Committee are now preparing a map and guide-book for the use of members. The Association Post-Office will be established in the Academy of Music, under charge of General Huidekoper, postmaster of Philadelphia, and letters and packages bearing the letters A. A. S. will be there delivered. Special free telegraphic facilities for personal messages have been secured, including the use of the transatlantic cable for the benefit of foreign guests. The transportation of specimens, apparatus, etc., will be attended to by the Local Committee, who will give particulars on receiving applications through the Local Secretaries. Every possible care will be taken of objects sent for exhibition or use during the meeting, and a suitable hail will be provided for them. It is hoped that members having specimens or apparatus of particular interest will exhibit them at the meeting.

The meeting will be called to order, in general session, at ten o'clock, on Thursday morning, September 4th, in the Academy of Music, by President C. A. Young, of Princeton, who will resign the chair to the President-elect, Professor J. P. Lesley, of Philadelphia. After the adjournment of the general session, the sections will organize in their respective halls. General sessions and sections will be held on Friday. The vice-presidents of the sections will probably give their addresses during the day, and in the evening President Young will deliver his address at the Academy of Music, after which there will be a reception tendered to the members of the Association and their invited guests by the Local Committee and citizens of Philadelphia. Saturday will probably be given up to excursions and receptions. The general programme for the rest of the meeting will be similar to that at previous meetings.

The headquarters of the Association will be at the Academy of Music, which is on Broad Street, in the center of the city, very near the station of the Pennsylvania Railroad and several large hotels. The sections will be amply accommodated in other halls in the immediate vicinity.

The offices of the Permanent Secretary and Local Committee, the Association Post-Office, etc., will be at the Academy of Music after September 1st; previous to that they will be at the Academy of Natural Sciences. The Permanent Secretary will establish his office in Philadelphia on August 22d.

The British Pharmacopœia.—Dr. Robert Farquharson writes as follows to the editor of the "British Medical Journal": "Understanding that the Medical Council have it in contemplation to edit a new edition of the 'British Pharmacopœia,' I venture to express a hope, although not a very confident one, that something may be done to bring this antiquated volume into harmony with modern usage. By this I do not mean the revision rendered necessary by self-progress, and the introduction of those new drugs which have established their claim to popular favor; but I plead for a drastic and thorough overhauling of every page, in the true spirit of radical reform, and the summary ejection of many useless and superfluous things. The vigorous application

of the pruning-knife might reduce the size of the book by at least one third without impairing its efficiency; and the student will bless the day which has released his overloaded memory from some part of its burden. Nothing in connection with *matéria medica* has surprised me more than the way in which many so-called remedies, which no one ever dreams of using, and which probably could not be found in case of need, are permitted to cling, with the conservative tenacity of barnacles, around our modern text-books. Some mysterious rumor of special virtue, handed down from edition to edition, forms the excuse for the retention of these effete articles; and, when they are driven out of the fastnesses of gout and rheumatism, they may safely take refuge under the shadow of 'chronic spine-diseases,' from which it is hardly worth any one's while to dislodge them. Hence, we have *dulcamara* and *mezezon*, and *sassafras* and *sarsaparilla*, and *hemidesmus* and *canella*, and *cusparia* and *krameria*, and *serpentaria*, and other rubbish of the kind, reverently greeted by professors on their lecturing rounds; and woe be to the student who does not possess at least a nominal acquaintance with them.

"I would at once throw these and many other relics of a decayed superstition overboard, and would especially ask for the expulsion of the *enema tabaci*, whose use might fairly entitle any practitioner to the honors of the Old Bailey, of all the preparations of *conium* but the succus, of all the vapors, of *aqua chloroformi*, and of many of the more fancy varieties of iron and mercury. Opinions may differ about phosphorus; mine decidedly is that it is an overrated remedy, uncertain, dangerous, and, basing its reputation on somewhat ambiguous evidence, I should like to see it deprived of its official sanction; but if it be too much to expect that it shall disappear from the '*Pharmacopœia*,' may I venture to hope that some preparations may be devised which may enable us to prescribe it in an unaltered state? Regard for your space prevents my going into greater detail, but I make this appeal principally in the interests of the student, whose mental capacity is unfortunately unable to keep pace with the expansion of modern science, but who is expected to know everything about everything which his curriculum includes. Chemistry may tax the devotion of a life, but he must know it all; physiology might well claim his undivided energies, but it must take its place with other objects of study; and four short years have to do it all. If we can take off some part of this crushing burden, we shall indeed be benefactors of our species; and it will be something if we can tell the rising generation at our medical schools that fifty or sixty drugs, which they were formerly called upon to recognize, have now been consigned to the limbo of the past.

"May I conclude with a word about doses? I have always regretted that the '*Pharmacopœia*' should have made any reference to this subject, because their directions, to be of any use, should be entirely authoritative, and I am sure I am correct in saying that no practitioner goes to that source for his information and guidance. It is not to be supposed that any charge of malaprapaxis could be sustained if misadventure followed the use of a drug in quantities larger than that officially recognized; and all that now happens is the occasional inconvenience and discredit of having our prescriptions sent back by the druggist for revision if he thinks that the dose is too large. This may happen to any one who orders more than ten grains of quinine, twenty minims of tincture of belladonna, thirty grains of bromide of potassium, ten grains of iodide of potassium, eight minims of liquor arsenicalis, or thirty minims of tincture of perchloride of iron; and on this question, at least, opinion will be unanimous that revision is required."

Beer-drinking and Heart Disease.—The most essential factors of the living heart are unquestionably its neural and muscular elements. It may seem superfluous to assert so plain a truth; nevertheless, the necessity of bearing this fact in mind is demonstrated by every-day experience. If the heart be the subject of debate among medical students at our hospitals, how much do we hear of the murmurs and how little of the condition of the myocardium! Our present object is to draw attention to a class of cases which have not received the wide study they deserve. Idiopathic hypertrophy and dilatation of the heart are not phrases which carry their own credentials. To speak openly, the term "idiopathic" is regarded by scientific physicians as a pleonastic cloak for our ignorance. Cardiac hypertrophy of idiopathic

sort is said to be of common occurrence in Munich, as compared with other cities. Spatz found that, of 638 men, no less than 35 were affected with so-called myocarditis. Among 433 women there were 23 cases. Of 290 men, between the ages of thirty and sixty, there were 41 cases of myocarditis, or about 14 per cent. Of 144 women, at the same period of life, only 10, or about 7 per cent., were affected. Hermann's reports showed 49 cases of muscular disease of the heart in the male among 305 necropsies, while only three females had this condition. Von Buhl looked on these instances of cardiac hypertrophy as the result of chronic myocarditis, which usually ended fatally in consequence of fatty degeneration of the muscle. Bollinger, who has re-studied this subject, can not find any evidence of inflammatory changes or fatty degeneration. At his suggestion, Schmidebauer undertook to establish the extent of the prevalence of cardiac hypertrophy in Munich upon a statistical basis, with a view to making clear its causation. Among 1,000 necropsies there were 46 cases (32 men and 14 women) in which the cause of death was attributed to simple hypertrophy of the heart. As an associated condition, not as a cause of death, idiopathic hypertrophy of the heart was found in 33 other cases (23 men and 10 women). All cases of enlargement of the heart due to lesions of the valves, or disturbances of the pulmonary circulation, or associated with arterial sclerosis, or granular kidneys, were said to be excluded. Some of the cases were attributed to prolonged muscular effort. But the greater number were believed to be due to habitual excess in beer-drinking, attended with a true plethora, or overcharge of blood. It is argued that the habitual consumption of beer in large quantities tends to enlarge the heart by the direct action of the alcohol on its tissues, by the increase in the amount of fluids in the body, and by the belief that the nutritive ingredients of the beer are easily assimilated. Statements are made to the effect that the average weight of the heart in men is relatively greater in Munich than elsewhere. Both sides of the heart participate in this hypertrophy. It may naturally be asked how it is that sufferers from simple hypertrophy are prone to die of an affection which apparently contains no fatal elements in its composition. The phrase simple or idiopathic hypertrophy is in this respect misleading. Exhaustion of the nervous apparatus without obvious disease of the muscular tissues is the proffered explanation of the fatal result—an explanation not altogether free from valid objections. As an interesting fact it may be stated that during the year 1882 the average amount of beer consumed by each person in Germany ranged, in different districts, from 54 to 186 litres, in Bavaria it reached 233 litres, and in Munich 432.—*Lancet*.

Splenectomy.—According to the "*Medical Times and Gazette*," Dr. Kéberlé recently related to the Société Médicale de Strasbourg his second case of splenectomy, performed on a woman, aged forty-six, for an hypertrophied spleen, the result of intermittent fever. Both this and his first case were examples of the largest spleens that had ever been removed, the organ in both cases resting on the pubes, while there was also great enlargement of the liver. The spleen in the present case measured 40 centimetres in length, being only five centimetres less than in the other case, in which the organ, when emptied of its blood, weighed 6,800 grammes. The affection had run a rapid course of less than a year and a half, and at last there was effusion into the pleura, pericardium, and peritonæum, the patient being much emaciated and cachectic, passing but a small quantity of urine and exhibiting a temperature of from 102° to 104° F. As in the former case, there was great adhesion to the diaphragm. In that case fatal hemorrhage had taken place from the vessels of the adhesions, but in the present case this was prevented by three ligatures on the splenic vessels. As a consequence of the constriction caused by these, arterial hemorrhage took place from a large number of cutaneous vessels along the line of incision, where complete hemostasis had prevailed for more than an hour. A great deal of blood (which was very plastic and rich in coagulable fibrin) was in this way lost; but, in spite of this, the patient rallied well for a while after the operation, which lasted nearly three hours; but in about an hour after its completion she was seized with convulsions and died. This case is another example of the danger of removing large spleens; but the operation was only performed at the woman's insistence, after its danger had been completely explained to her.

Original Communications.

OLEATE OF COPPER:

ITS EMPLOYMENT IN FIVE HUNDRED CASES OF PARASITIC DISEASE OF THE SKIN.

WITH ANALYTICAL TABLES.

By F. LE SIEUR WEIR, M.D.,

CLINICAL PROFESSOR OF DISEASES OF THE SKIN IN THE MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA; DERMATOLOGIST TO THE COLLEGE HOSPITAL; MEMBER OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY, THE PENNSYLVANIA STATE MEDICAL SOCIETY, THE MEDICO-LEGAL SOCIETY, ETC.

WITHIN the last few years the treatment of vegetable parasitic diseases of the skin has received an impetus never before known, owing to the introduction of certain new remedies and new remedial measures. Perhaps it may not be altogether correct to speak of the remedies collectively as new, for some of them are but old friends under a new and more efficient guise. We all remember the old-fashioned cure for ringworm, consisting of a copper penny dipped in vinegar, extant even to this day; but very few who used it in times past would recognize their ally in the elegant ointment of the oleate of copper, now coming so prominently before the medical profession. The legitimate successor of the "penny-vinegar" cure, the newer preparation not only combines all the essentials of the latter, presented in a neat and available form, but offers the means of effecting cures with far greater uniformity of results than has ever been obtained before, no matter what the remedy. Treatment of diseases of the skin due to the presence of a vegetable parasite has not heretofore yielded the most satisfactory results, and this has been due to several causes. First of these was the lack of a drug or preparation which could be looked upon as a *specific*, or something nearly such, and which, accordingly, could be depended upon as capable of invariably effecting a cure. Other reasons, less important, were, and are yet, not wanting to explain why success failed to crown the efforts of the therapist, but such do not fall within the scope of this paper. The oleate of copper, as already intimated, is a preparation of recent origin, being evolved even later than the popular and efficient oleates of lead, zinc, mercury (the latter of which is the only one official), etc., themselves dating back but a few years.

The form under which all of the oleates made their first appearance was as solutions of the oxide of the base desired in simple oleic acid, and the United States Pharmacopœia so directs that oleate of mercury shall be prepared. But it will not require an expert knowledge of chemistry to see that such a combination, lacking as it does a reaction, not to mention the entire absence of water, is not a salt at all, in the strict chemical sense of the term.

Instability in strength was not the least of the objections urged against these preparations, not to mention chemical changes which rendered their application inadmissible, if, indeed, not highly improper. Physicians, and dermatologists especially, need not be told of the effects of a rancid ointment.

Recognizing these and other defects, and owing to the

numerous complaints of myself and others who had made extensive use of the oleates, my friend, Dr. Wolff, became desirous of furnishing an article which would overcome objections and at the same time be *chemically pure*. To this end, then, the doctor commenced a series of experiments which finally resulted in the production of an oleate which fulfilled all the required indications. An extended description of the process of preparing the oleates in general is not pertinent here, and a condensed account of the manner in which the cupric oleate is made is alone appended:

"One part of Castile-soap (sodium oleo-palmitate) is dissolved in eight parts of water; the solution so obtained is allowed to cool and stand for twenty-four hours, when there will be a considerable deposit of sodium palmitate, while the supernatant liquor, containing mostly sodium oleate, is drawn off and then decomposed with a concentrated solution of a metallic salt (cupric sulphate), which, if obtainable, should contain no free acid to prevent the formation of free oleo-palmitic acid. The heavy deposit of oleo-palmitate so derived is strained off, pressed out in the strainer, and the adherent water evaporated in a water-bath; after this it is dissolved in about six or eight times its quantity of petroleum benzin, and the insoluble palmitate is left to subside while the solution of oleate decanted therefrom is filtered off. The benzin evaporated will yield an oleate that is entitled to that name, as it is a chemical combination and will remain stable and efficacious."*

Such, then, is the method by which a good and true oleate of copper may be produced. This product would seem to be all that is required, and, indeed, in my experience, it has answered every purpose most admirably, presenting none of the objectionable features before alluded to. Further comment would therefore seem superfluous. It may be well to remark, however, that such an oleate of copper, as well as all other oleates thus prepared, is, to all intents and purposes, a saturated solution—that is, we have in this unctuous substance the analogue of a saturated solution of potassic chlorate or other salt. Those who have noticed the directions in the Pharmacopœia for making oleate of mercury (mercury, 10 parts; oleic acid, 90 parts) will see at once what a large amount of acid is left free after the solution of the base. No such excess is observed in an oleate prepared after the process above described, and the substance is practically of *full strength*. In its application, therefore, dilution is necessary, and this is easily accomplished by the addition of cosmoline, so that the varying strengths of ung. cupri oleatis (so called)—10, 20, 30, 40, 50, or any per cent.—may be readily encompassed by the means stated. Just here it may be well to remark that the practice of speaking of a 10, 20, 30 (or greater) per cent. ointment is altogether unnecessary, and not infrequently proves embarrassing. There is no more necessity for thus designating an oleate ointment than there is for speaking of a diluted citrine ointment as being such and such a per cent., according to the amount of dilution. Thus, for example, a diluted citrine ointment of, say, the strength of *two drachms* to diluent *six drachms* would, according to

* Wolff: Paper read before the Philadelphia College of Pharmacy.

this acquired nomenclature of the oleates, be expressed as a 25-per-cent. ointment. This is easy enough so long as even numbers occur, but when fractions are necessary the system is at once faulty. It has long been a source of wonder why physicians should adhere to this useless and complicated system when a simpler method is at hand, and it gives me pleasure to refer to a recent article by Dr. Stelwagon, in which the same objection is treated of fully.* It may be added that the same objection applies in speaking of the oleates in their pristine state as being of a certain per cent., and, indeed, it was in this connection that the objection arose originally.

Having at command, then, so admirable a weapon as this preparation of copper in combating those disfiguring diseases known as the parasitic, it remains to be seen how wide is the scope of its usefulness, and how it may be used to obtain the best results.

As has already been stated, the oleate of copper is a comparatively recent addition to the family of oleates, and, had not exceptional opportunities presented themselves for experimentation, I should not feel justified in ascribing to it the decidedly curative properties that I now so freely concede to it.

I am aware that some others have not accorded it the almost specific action that I attach to it, and I can not understand why the drug has not yielded in their hands the expected results, unless it be that a sufficiently strong ointment has not been used.

The exceptional opportunities just alluded to have enabled me to observe its curative action in types of parasitic disease of the skin not, to my knowledge, heretofore treated with it; or, if they have been, certainly not to any extent. Trichophytosis, both of the head and of the body, has been the disease in which the remedy has found its greatest use heretofore, and those who have employed it here will agree with me, I think, in speaking well of it. My investigations have led me to treat no fewer than seven different forms of parasitic disease of the skin with the preparation. By this I mean practically seven different forms, although in theory they number only four, since several of them are caused by the presence of the same parasite. The scope of usefulness of the remedy, then, so far as my observation goes, is confined to practically seven diseases, viz.: *Tinea tonsurans*, *T. circinata*, *T. kerion*, *Eczema marginatum*—all caused by the same parasite; *T. sycosis*, *T. versicolor*, and *T. favosa*—each due to a separate parasite.

Prior to adopting the copper my usual course of treatment embraced the drugs usually employed by dermatologists, the results being those ordinarily obtained by others. The principal drugs used are, as is well known, mercury, in the form of either the mild or the corrosive chloride, ammonio-chloride, red oxide, yellow sulphate, or ointment of the nitrate, tincture of iodine, sulphur, tar, carbolic acid, tannic acid, and bichlorate and hyposulphite of sodium. These, being the ones oftenest employed, answered their purpose very well in my hands; but the chief difficulty was the long time required in effecting a cure if the case happened to be at all obstinate. With the advent of the copper oleate this

trouble was largely overcome, and prolonged trial has demonstrated the possibility of still further increasing its efficacy by gradations of strength. My plan of treatment is as follows: If affecting a hairy part, first of all cut off the hair close to the skin wherever a diseased patch shows itself, the clipped area extending at least one inch, and oftener one inch and a half, beyond the margin of the advancing lesion. Having done this, the parts are then anointed with oil, fluid cosmoline (petroleum), or glycerin, or a bread-and-milk poultice is applied. This for the purpose of dislodging scales or crusts if any be present. For the same purpose, when very much scurf or actual dirt is accumulated upon the parts, as is not infrequently the case, especially in public practice, I occasionally direct the parts to be thoroughly scrubbed with Castile-soap and warm water. Then an ointment of the oleate of copper, of a strength suited to the severity of the case, is prescribed and ordered to be rubbed into the diseased patches, gently but thoroughly, so as to procure as complete and rapid absorption as possible. If an exposed part, as in the case of ringworm of the head, it may be lightly covered with some appropriate material, or left bare, as the judgment and exigencies of the case dictate. The process of inunction should be repeated at least twice daily, this being usually amply sufficient. Unless an accumulation of scab-like substance should appear, it is not necessary nor even desirable that the part be washed except at infrequent intervals. No set prescription is used—that is, in relation to strength—some cases requiring but a mild application, while others call for a very strong ointment. The following prescription illustrates the average range of strength in which it is most frequently employed:

R Cupri oleatis, ʒj-vj;

Ung. petrolei, q. s. ad ʒj. M.

As will be observed, the quantity of oleate varies from one to six drachms in an ounce. In mild cases the first serves a very good purpose, fulfilling easily every indication. This, *en passant*, according to the prevailing method of designating oleates, would be a 12½-per-cent. ointment! For the severe and obstinate forms the six-drachm ointment (or even stronger) is, of course, indicated. Between these two extremes I choose a strength which the judgment indicates as being best suited to the case. Not infrequently a change for the better is observed after the second or third application, and, more especially if the case be of a mild character, often seven or eight days suffice for a cure. If, however, it is severe, a longer time is required, varying from ten days to three weeks. Exceptionally obstinate cases require even longer periods than this, but these are comparatively rare.

According to the statistics furnished by the superintendent of a charitable home for children under my charge, the shortest time required for cure was one week, which is a very fair result in consideration of the fact that the patients were not seen personally by me, but treated by the matron from my written instructions.* Less time than this has sufficed where the person treated has been under immediate supervision, for then the strength of the ointment can

* "Med. and Surg. Reporter," Phila., vol. i, No. 11, p. 824.

* All the cases in the institution referred to were of ringworm.

easily be increased if the circumstances of the case require it. As showing another result, the same report refers to another case which was under treatment for a period of upward of *six weeks*. Here the prolonged recovery is easily explainable by the ointment prescribed not being strong enough. A prescription for the ointment, containing a fixed quantity of copper oleate (the strength can not now be recalled), was sent to the home, and this was used for all cases indiscriminately. Thus the tardy recovery of a few, the more obstinate, may be easily accounted for. The same thing also occurred in another public institution, also under my charge, the patients not being seen personally but treated by letter.

The ointment is the form in which the copper oleate is used. Some months ago, however, at my suggestion, Dr. Charles L. Mitchell, of this city, who manufactures the so-called gelatin-plasters, prepared some oleate of copper in this form. The plaster thus prepared was used with signal results in a few dispensary cases, the effect being all that could be desired. The experiments were not sufficiently extended, however, to enable me to place the oleate in combination with gelatin on a plane with oleate ointment.

In preparing the following tables no inconsiderable pains have been taken to insure against inaccuracies, and, in consequence, each of the five hundred cases noted therein is believed to be absolutely correct. Up to January 1, 1884, no fewer than five hundred and twenty-three cases came under my observation; but, for purposes of convenience, the twenty-three odd cases have been eliminated as follows: Five were "lost sight of," three were so much complicated by syphilis as to render them worthless for tabular use, one was, through a mistake, not entered upon the clinic-book until long after recovery, and then only from the memory of my assistant, while the remaining fourteen have been stricken off for purposes of convenience in tabulation. With these preliminary remarks Table I is submitted:

TABLE I.

Analysis of Five Hundred Cases of Skin Disease treated with Cupric Oleate.

DISEASE.	Parasite.	PRIVATE PRACTICE.			PUBLIC PRACTICE.			Grand Totals.
		Males.	Females.	Total.	Males.	Females.	Total.

		54	30	84	301	115	416	500

Some months ago a medical gentleman of this city wrote me asking about my experience with the copper oleate. In response I gave him a condensed table of cases which embraced the major portion of those here tabulated, and which was, I understand, used in the preparation of a short article on oleate of copper.* Since then more cases have been added, until they have reached the present large number. The table just referred to, as compact as was then possible, has now been subjected to rigid examination and revision, and arranged in a manner more easily understood and more convenient for reference.

PRIVATE PRACTICE.

Of the total number, eighty-four were private cases, as will be seen by reference to the table, and these comprised the different diseases in about the usual per centum of occurrence. The cases of ringworm of the head were all of the usual type, some being, however, extremely severe, while the major portion were ordinarily mild. Most of them (about 75 per cent.) occurred among very young children,† the youngest being but three months old, while the oldest had reached the age of fifteen years. The average age was about seven years and a half.

The two cases of kerion occurred in adult males and presented nothing unusual. Indeed, it is questionable if these cases of kerion, either in private or public practice, ought to appear here, being so nearly allied to the preceding disease. Their presence will, however, at least serve for variety.

The twenty-three instances in which the lesions occupied the body were observed mostly in adults, the proportion being about 70 per cent. The youngest was four years of age and the oldest forty-six, the average being twenty-five years. The three cases of eczema marginatum, classed therewith, were typical ones, the lesions being quite extensive and very well marked.

Of the eight cases of barber's itch it will be noticed that one occurred in the person of a female. This subject, married, and aged forty-six years, was unfortunate enough to be the possessor of a beard of no inconsiderable growth, it being thickest upon the upper lip and the chin, and required the daily use of the razor. The hair was light in color, otherwise even the daily shaving would not have concealed her unnatural ornament; as it was, the hairs were not altogether unnoticeable. Her razor needing sharpening, her husband took it to a barber, who, after giving it the necessary edge, probably used it upon a customer suffering from the disease. The lady could not account for her condition in any other way, and the hypothesis seems very probable.

The three cases of pityriasis versicolor were unimportant, and require no mention other than that they yielded readily to treatment.

Only one case of favus was met with in private practice; nor is this at all singular when we consider what a comparatively rare disease it is in this country.

Of the entire eighty-four cases of parasitic disease oc-

* "Jour. of Cutan. and Ven. Dis.," New York, vol. i, No. 14, pp. 438, 439.

† All under twelve years of age being classed as *children*.

curing in private practice it may be seen that about 86 per cent. were caused by the *Trichophyton tonsurans*, thus showing the marked predominance of this parasite over all others; and it may be further remarked that this parasite stands in the same relation to dermatophytic diseases as eczema does to skin diseases in general.

It is proper to state, however, in the present connection, lest this very large per cent. should be understood as always obtaining, that the number of cases referable to this parasite is somewhat greater than is ordinarily seen, owing to two families under treatment having thirteen children—seven in one and six in the other. Without even these comparatively large families, the per cent., in relation to the whole number, would still be large, and about what is ordinarily seen.

PUBLIC PRACTICE.

As in private experience, ringworm, properly so called, is far more prevalent than any other disease of the epiphytic group.

In the first group it will be seen that three hundred and eighty-nine cases are classified. Of these the cases of so-called ringworm of the head presented no feature worthy of special notice in this place. The youngest person thus affected was said to be six months of age, while the oldest was sixteen years, the average age being a little over eight years. As in the preceding instances, considering all persons children who are twelve years of age or under, it was found that about 80 per cent. of the persons thus attacked were children. Fourteen cases of kerion were observed; they occurred in adults—ten in males and four in females. They were all dispensary cases. Ringworm of the body, following the general rule, was noted as occurring largely in the adult. The proportion was not, however, noticeably large, being about 68 per cent. The youngest person thus affected was aged three years and the oldest forty-one years, the average age being about twenty-two years. Of the twenty-one cases of trichophytosis cruris, nineteen were in the adult males and presented nothing unusual. The remaining two cases, however, were in the persons of adult females, a rather uncommon circumstance, since, although others may have occurred, these are the first I ever saw or heard of. I do not see why the disease should be almost exclusively confined to males; indeed, considering these two cases etiologically, there would seem good reason for its occurrence in the female as frequently as in the male, if not oftener. Both of the subjects referred to were married, aged, respectively, twenty-one and thirty years, and the mothers of several children. In both instances no attention to personal cleanliness had been paid, and this, together with markedly acid secretions from the genital regions, and, in one case (the worst one), a very acrid leucorrhœa, had been amply sufficient to originate the disease.

Sixteen instances of sycois parasitica came under observation. A few were inclined to be severe, and had been rebellious to previous treatment, but the major portion were ordinary cases. For obvious reasons, the disease occurred in adult life, hence any note of age is unnecessary.

Nothing especially worthy of mention was seen in the five cases of tinea versicolor, nor in the six cases of favus.

Of the four hundred and sixteen cases thus met with in public practice, it will be observed that no fewer than three hundred and eighty-nine, or about 93·5 per cent., were caused by the *Trichophyton tonsurans*. This exceedingly large per cent. is, at first sight, rather surprising, for the analyses and compilations of different authors show it to be about 75 or 80 per cent. The larger part of the cases herein considered were drawn from public institutions, where large bodies of children and young adults were congregated, and similar statistics of other writers will, I think, show as high a per cent. in this regard as those herein set forth.

The following table has been prepared that the relative frequency of these diseases may be better shown:

TABLE II.

Showing the Relative Frequency of each Disease and its Per Cent. in Relation to the Whole Number.

DISEASE.	Males.	Females.	Total.	Per Cent.
Tinea tonsurans (proper)	212	73	285	57
" circinata (")	76	60	136	27·2
" cruris (eczema marginatum)	22	2	24	04·8
" sycois (barber's itch)	23	1	24	04·8
" kerion (modification of T. tonsurans)	12	4	16	03·2
" versicolor	5	3	8	01·6
" favosa	5	2	7	01·4
	355	145	500	100

This table simply shows the very large preponderance of ringworm of the head over any other form of vegetable parasitic disease of the skin; and 57 per cent., as there shown, of the whole number was caused by the ravages of the *trichophyton* in that situation. While it is singular that so high a percentage of a given quantity may be reached, it is yet more singular, if not astonishing, that, when we come to estimate the total morbid lesions contained in the table, for which this parasite is responsible, we find them to be the equivalent of 92·2 per cent. ! This is enormous, and shows that, of all the various forms of vegetable parasites, the *Trichophyton tonsurans* is by far the most prevalent.

Of the four hundred and sixteen cases seen in public practice, the greater portion, as elsewhere stated, were encountered in institutions having as inmates large numbers of children.

To afford a better idea, the following arrangement has been adopted:

Three charitable institutions, containing, respectively, {	155 inmates.
64 "	
39 "	
One private day-school	41 "
Cases seen in the public and private practice of other observers (but never before published)	39 "
Dispensary service	78 "
Total	416 inmates.

The "three charitable institutions" above referred to furnished, as is evident, by far the larger number of cases. The first is, I understand, a sort of foster-home for children, situated in one of the extreme Western States, and sustained by county aid and voluntary contributions jointly. The

second is altogether a private home—private in the sense that it is supported by voluntary aid only. It is situated in a neighboring State. Regarding the third, I am, through the kindness of Miss S. M. Boufoy, the efficient matron, enabled to give as much as may be necessary. This school numbers, as above stated, thirty-nine inmates, and is situated in Greensburg, Ind.

In neither the first nor the third instance was I enabled to see the patients personally, owing to the distance; and I was therefore compelled to rely upon the accuracy of description of the respective superintendents. In both cases this was accomplished without difficulty, the diagnosis of "ringworm" being easily effected, and *proved* by the uniform recoveries resulting from treatment. The "private day-school" is located in one of the suburbs of this city, and contains, as stated, forty-one inmates. The Boards of Managers of this school and the first two charitable institutions in the foregoing classification refuse to allow any mention of their names or location, doubtless through fear that, if it became known that a contagious disease had broken out among the pupils, public aid or patronage would be suspended. Thirty-nine miscellaneous cases were seen in the public and private practice of numerous medical friends by invitation, and are, for obvious reasons, appropriately classed under the head of public practice.

Seventy-eight cases came under my personal observation in hospital practice. They comprised cases of each of the seven diseases considered herein, and showed the usual variation from the very mild to the violent type.

It should have been added in connection with the schools, both public and private, that no other parasitic disease than *tinea tonsurans* (and its congener, *tinea circinata*) was present, so far as known.

It will be noticed that I have neither made any group of *tinea tonsurans* et *circinata*, nor, thus far, made any mention of such a one; this is for the reason that such cases—of which there were, so far as I could judge personally, a moderate number—were classed off according to the part most affected. For instance, if the lesion occupied the head to a more marked degree than the body, the case was immediately grouped under "ringworm of the head," and so on. Such grouping facilitates classification and avoids any confusion.

It now remains to consider the *application* of oleate of copper upon this class of skin diseases, both therapeutically and comparatively.

Following the general plan as laid down elsewhere in this paper, the hair (when the head was affected) was cut close, the scalp thoroughly cleansed of dirt, scabs, or scales, and an ointment, composed of copper oleate and cosmoline, in a proportion appropriate to the case, applied to the parts twice daily, the whole being covered by some light material.* No variation from this plan is practiced in kerion. The same holds true in *tinea corporis*, excepting that there is, of course, no hair to cut. In consequence of the absence of hair from the affected parts, the disease in this situation is more amenable to treatment, and tends, there-

fore, to recover more rapidly, and, in the cases under consideration, this theory was amply borne out.

The cases of trichophytosis cruris, or eczema marginatum, occurring in the male, were treated with a mild ointment of oleate of copper, and in every instance with entire success. As a rule, these cases do not need a strong copper ointment; at least such has been my experience. The two females thus affected were dispensary patients, and, owing to their generally bad hygienic condition and manifest indifference to the ordinary rules of cleanliness, it is not at all surprising that they should have been thus affected. In one case, that of the younger of the two, more attention to the care of the person greatly improved the disease, in addition to which the correction of the acidity of the vaginal discharges, the exhibition of appropriate tonics internally (notably iron), and a quite mild ointment of the copper, sufficed to effect a ready cure. The other case was more obstinate, owing, in all probability, to the acidity of the profuse leucorrhœa present. Basing the ætiology of the disease in this instance upon the latter, the root of the difficulty was attacked at the outset. Examination showed quite a good deal of retroflexion of the uterus, with a considerable degree of prolapsus, together with a subacute endotrachelitis of some severity. As quickly as possible these were all relieved by the usual means, and, after the leucorrhœa had largely abated, a moderately strong copper ointment was given the patient. So well planted was the disease, however, that a much stronger ointment was required.* This had the desired effect, and the patient was finally discharged with the injunction—which had also been administered to the other sufferer—"to be more careful of herself in the future." In neither case was the extent of surface involved very large, but it occupied a somewhat irregularly shaped area upon the inner aspect of either thigh, extending somewhat beyond the line of contact of the two limbs in both the anterior and posterior direction, and, had the patches been symmetrical in outline, would have measured probably from three and a half to four and a half inches in diameter.

Of the cases of trichophytosis barbæ, only three were sufficiently obstinate to cause any difficulty, and these were promptly met with a stronger ointment. All the others yielded readily. I am inclined to think, after long trial with each, that the cupric oleate yields quicker and better results in the treatment of this disease than any other application. The social position of my bearded lady patient who contracted this malady being in the higher walks of life, and the stiffness and quantity of the beard being conspicuous, notwithstanding its light color, her situation was, indeed, a most mortifying one. After the cure of the skin disease was effected, I undertook, at her request, the radical removal of the abnormal appendage. Not having knowledge of any so-called depilatory which would remove superfluous hair permanently, I called in the aid of electricity, and, am happy to say, succeeded, by the process known as electrolysis, in removing nearly every hair from the exposed portions permanently. The sittings were numerous and, I need hardly add, tedious; but, by much bravery and persistence on the part of the patient and some patience on that

* A full description of the mode of application is given elsewhere in this article.

* Cupric oleatis, ℥vj; ung. petrolei, ℥ij. M.

of the operator, the object was at last a *fait accompli*, and the lady made happy.

All of the cases of pityriasis versicolor were mild, and yielded readily to a weak ointment. My experience with the copper in this disease is limited to a rather small number of cases, and I am, therefore, not prepared to say that the drug in this variety of skin disease is superior—at all events, not decidedly so—to the mercurial or sodium salts. All I feel sure of is that it answers a very good purpose, and in the cases treated with it the mission was accomplished as rapidly, probably, as it would have been by other means. The few cases of tinea favosa encountered presented the usual yellowish, umbilicated crusts and honey-comb appearance of the scalp. This disease, as is well known, may exist upon other parts of the body supplied with hair, but its usual seat is upon the scalp, and in none of the cases under my charge did it appear elsewhere than upon the latter situation. Most of the cases occurred in the persons of young adults. Time was when this disease was considered almost if not quite incurable, and treatment was largely given over to quackery. Schönlein's discovery of the parasite which to-day bears his name revolutionized the treatment, and, in consequence, recoveries took place under more enlightened and scientific treatment where before the sufferers were either compelled to endure the affliction for years as best they could, or else submit to the brutal method employed by the notorious Mahon Brothers—a couple of French charlatans—which consisted in applying a large pitch plaster to the scalp and afterward violently tearing it off, bringing hair, and, not infrequently, portions of the skin along with it. Sulphur or mercurial ointments, hyposulphite of sodium, and a sulphurous acid lotion, together with epilation, have heretofore been acknowledged to be the best means of attacking the enemy in his stronghold, and I must bear testimony to its efficacy. The preparation of copper used in this series of experiments has in these cases afforded some encouragement. It must be confessed that the cure was considerably longer in being effected than by the older method, and the reasons for the delay will be seen presently.

The oleate was used in varying strengths—from one drachm to six drachms to cosmoline enough to make an ounce—according to the exigencies of each particular case. From time to time, more for sake of variety, perhaps, some form of mercury, preferably the oleate (not the official preparation), was incorporated; and, indeed, this was frequently done in all the other cases as well. It may appear to some of my readers that the mercurial was the potent agent, but I reply that in every instance where it was so used the case was given ample time first to respond to the copper alone, that any such objection might be groundless.

But what of epilation? Diseases of the skin of the character under consideration have, when attacking a hairy part, had epilation largely employed as a more or less necessary adjunct to the treatment. Ringworm of the head, in the belief of many practitioners, requires that this process shall be employed almost if not quite universally, although of late years it must be said this belief is rather losing ground. While the process has been practiced largely in parasitic affections of the head, its usefulness has been far more ap-

parent in barber's itch; indeed, I may say that, by the ordinary methods of treatment, hardly a case of this disease is considered curable except epilation be employed in conjunction with the medical applications. These remarks apply equally to favus, and the first crude application of the principle is seen in the barbarous method of the French pretenders before alluded to. If I were asked to name one advantage possessed by copper oleate over all others, I should unhesitatingly say it *obviates the necessity of epilation*. My experience with it (the oleate) has satisfied me that epilation under its use is *rarely necessary*.

In treating ringworm of the head with copper oleate I have never yet had to perform epilation except when the lesions involved the eyelashes; here there is no help for it, as the oleate has an unfortunate tendency to attack the conjunctiva, and, when brought in contact with it, may even set up a smart inflammatory action therein. In such cases I explain the situation to the patient or his friends, and, having thus secured as much intelligent co-operation as possible, I remove a few of the lashes and persist in the application of the ointment, making the latter, however, as weak as circumstances will consistently allow, meanwhile keeping a close watch upon the eyes. Coming in contact with the eyeball produces smarting, which is, of course, increased in direct proportion to the strength of the ointment.

The modification of tinea tonsurans known as kerion does not require epilation any more than ringworm of the head proper.

In tinea sycosis epilation is more frequently necessary than in tinea tonsurans, but even here it is practically uncommon.

Favus may, like the other parasitic diseases attacking a hairy part, be cured without epilation. I am convinced that recovery may take place much more quickly if epilation be practiced in conjunction with the copper ointment. Without it, owing to the hairs being allowed to remain *in situ*, the cure is longer in being effected. Loose hairs, or those which are thoroughly dead, drop out, or may be easily and painlessly removed. By the penetrating quality of the remedy the seat of disease is reached, the plant itself destroyed within its very bed, the partially good hairs or those but just beginning to be involved in the morbid process are saved, and the patient spared much suffering from their forcible removal.

To sum up, then, I may state that, while epilation may be, and undoubtedly is, necessary in what may be denominated isolated cases, yet I do not think I use too strong language in saying that *epilation is rarely necessary in parasitic diseases where copper oleate is used*.

The comparative length of time required to effect a cure is variable. Ringworm of the head and body is eradicated in from a few days to two weeks more quickly by the copper treatment than by the old procedure; barber's itch is relieved more promptly and decidedly than under the former plan; pityriasis versicolor is affected as readily as by other means, although, as before mentioned, the number of cases experimented with was not sufficiently large nor interesting upon which to base an absolute opinion. Lastly, in favus the cure is retarded if epilation is not used. This is

the only disease of this nature in which the remedy has not produced a more rapid cure than other drugs. But I need not point out, as counterbalancing this, the preservation of partially good hairs and the suffering avoided; the facts are self-evident. Using the five hundred cases as a basis, I think better and quicker results—speaking in general terms—are obtainable by the copper treatment of the parasitic diseases than by any other plan. No better evidence of its permanency is afforded than that every case enumerated in the foregoing table was relieved *entirely*, not a single relapse having come to my knowledge.

In almost all cases of disease of the skin, be it parasitic or not, the patient is physically below par, the general appearance as well as the system at large bearing evidence of the bad state of health which has originated the trouble (as it undoubtedly may do sometimes), or, if not this, predisposed to it. Manifestly, then, tonics appropriate to each case are imperatively called for; and he is a very poor dermatologist, as well as a conspicuously unsuccessful one, who ignores the influence of the economy at large upon diseases of the skin, and who, consequently, fails to afford the necessary assistance in maintaining a proper standard. Hebra, the exponent of the Vienna school, was an exception to this, for, while denying almost *in toto* any connection between the skin and the general system or special organs, he nevertheless demonstrated, during his brilliant career, a wonderful degree of success and skill in coping with this obstinate class of diseases. The proper supporting and reparative measures must vary, of course, with the exigencies of the case. Iron, quinine, and the bitter tonics generally are usually appropriate, and they should, moreover, be made up in as pleasant and palatable a form as possible. With the constant improvements going on in the domain of practical pharmacy, there are few drugs now in use that can not be made into a form both elegant and acceptable for internal administration. "Pleasant medicine" is more especially necessary in the case of children, for obvious reasons.

In my response to the letter of inquiry before mentioned, referring to the formation of furuncles, I said that I had "never observed any untoward effect, furunculosis or otherwise." I wish now to amend that statement by saying that, since writing the doctor to that effect, I have observed, in a limited number of cases, a tendency to the formation of furuncles of the variety usually known as "blind." The cases were not at all numerous, however—probably not exceeding six or seven, so far as known. It must be borne in mind that most of the cases here reported were not seen personally; but so very full and explicit were the several matrons or superintendents of the institutions in their letters to me that, had such symptoms as these arisen, they would have been sure to report them. Not to ignore even a slight point in the investigation of this remedy, I may add that in those instances in which furunculosis swellings did occur they developed after the application of the very strong ointment; but—and this is an interesting point—in many, if not all, the persons affected (with the swellings) there existed a more or less well-marked tendency to a strumous diathesis. In consequence of this significant fact, the question has suggested itself to

me whether the swellings would not have occurred with the application of any other remedy; if, indeed, they would not have presented themselves any way sooner or later through the aggravating influence of the morbid dermal state.

From one of the public institutions one case of boils was reported, and this is the sole case of the kind which I have ever known to reach suppuration. The case was, I believe, decided not to be one of ringworm, although it had been so classified in the beginning.* The patient's head presented the usual dry, scaly appearance so common to some stages of the disease, together with some falling of the hair, etc. In this case the application of the oleate occasioned the boils mentioned, "with a head or cap to each. On being opened, a core, like a little grub in appearance, was ejected, leaving a hole in the scalp. These little ulcers, or whatever they are, continue to reappear, and the head is much inflamed and feverish. The poulticing and vaseline have reduced the inflammation somewhat, however, and we have decided that the oleate shall be discontinued, the disease evidently not being ringworm." (Sarah M. Bonfoy.)

In concluding this paper it may be well to remark that unusual facilities have been accorded me for experimenting with the preparation in question. It is not often that the professional man meets with so large a number of special cases, and, lest a doubt might be entertained of the entire accuracy of the report, I hesitated long before committing the result of my observations to print. I have endeavored, and, I think, with entire success, to guard against any mistake or unfortunate statement.

The accumulation of data for such a paper as the present one, with the time and patience involved, has been, as may readily be supposed, a matter of some labor, and the author earnestly hopes that its presentation under this dress may not be without value from a therapeutical point of view.

ON THE PREVENTION AND TREATMENT OF PUERPERAL FEVER

FROM AN ETIOLOGICAL STANDPOINT.

By W. D. SCHUYLER, M. D.

(Continued from Vol. XXXIX, p. 605.)

ETIOLOGY OF PUERPERAL FEVER.

II. Concerning the degree of prevention which should be attempted against an attack of puerperal fever, we must be guided in our judgment by the likelihood of its occurrence, which, again, must be referred to the etiology of that malady. As more fully setting forth his views of its causation, Dr. Thomas refers to the report of the Berlin Obstetrical Society, whose committee, in 1877, as quoted by him, promulgated the following: "Under the names 'puerperal fever' and 'malignant childbed fever' are included a group of diseases occurring in childbed which vary greatly in their manifestations, but have this in common, that they are called into being by the absorption from the organs of generation of a material which gives rise to destructive

* A dispensary case has been placed to the credit of the institution referred to in the place of this case, so as to preserve intact the number of cases set opposite the school.

inflammation and fever. There are indeed a number of substances, mainly composed of organic materials in a state of putrid decomposition, which, when brought into contact with an open wound, set up inflammation in it, which extends to the neighboring tissues. *Puerperal fever is indeed nothing else than the infecting of fresh wounds, such as are found in every newly delivered woman, with these septic materials.*" (Italics mine.) "Thus every newly delivered woman is liable to suffer from the dreaded infective-wound diseases, which, in persons wounded under other circumstances, are called pyæmia, septicæmia, wound fever, blood-poisoning, purulent infection, etc., as soon as suitable septic materials are brought into contact with the genital organs." The manifest interpretation of the language of this report adopted by Dr. Thomas is very simple and direct. According to it, *puerperal fever*, including by this title a group of diseases occurring in childbed, *is called into being by absorption through the wounded generative tract of a septic material, mainly composed of organic matter in a state of putridity,*" and "*is indeed nothing else than the infecting of fresh wounds with these septic materials.*" And with regard to the nomenclature of this malady, "known under the name of puerperal fever, child-bed fever, lying-in fever, and under the titles of the various special affections which develop in its course—phlebitis, lymphangitis, etc."—Dr. Thomas would suggest, as conveying "to the student and to the practitioner a clear idea, in consonance with the teachings of modern pathology, the term 'puerperal septicæmia,'" which is a further declaration, from another point of view, in perfect harmony with his statement previously referred to, that "puerperal fever is puerperal septicæmia."

In the opinion of the writer, the steps and course of the pathological development, as set forth in the Berlin society's report, correspond exactly with the pathogenesis of puerperal septicæmia. And, if we recognize no other than an idiopathic form of puerperal fever, if we deny that there is another, a semi-specific, contagious variety of the puerperal febrile disease, then we can not object to calling "puerperal fever" "puerperal septicæmia."

But that that form of the puerperal febrile disease met with mostly in hospital obstetric services, in the lying-in wards of general hospitals, is nothing else than the infecting of freshly made wounds by the putrid decomposition of the products of gestation only, I am unwilling to admit. Lacerations result much too frequently that are not followed by puerperal fever to justify us in concluding that in such a pathogenesis—otherwise uninfluenced—resides its essential cause. The rule is that almost every woman who performs the parturient act is somewhat lacerated, and yet not in my private experience has that form of puerperal fever met with in hospital lying-in wards, which develops a propagating contagium, resulted once from this cause. Again, that hospital "puerperal fever" and "malignant childbed fever" have it in common that they are called into being by the absorption from the organs of generation of a material which is (simply, not otherwise impressed) only in a state of putridity—in view of the many cases in which the lochia are offensively putrid and no such contagious inflammatory fever results—is not to be accepted in the light of all observed facts.

From a consideration of all the evidence of experience, and because such a deduction is not impossible, it is reasonable to conclude that there are at least, ætiologically speaking, and therefore essentially, two forms of puerperal febrile disease, both of which result from the reception into the system of a poison through the generative tract; and that one arises from a *materies morbi* which is a sepsis *idiopathically generated*, and may be appropriately called "*puerperal septicæmia*," while the *materies morbi* of the other is a specifically developed contagium, a *special malaria*, a *heterogenic* principle, and the fever it sets up may be, categorically at least, designated "*puerperal fever*."

It is quite likely that the genesis of both of these forms of fever—concerning the existence of which much evidence might be offered—may arise out of more than one set of predisposing causes; that the contagious principle of *puerperal fever* may be developed from nosocomial lying-in emanations, and exist from and in epidemic and endemic states and influences; while the sepsis capable of exciting *puerperal septicæmia* (idiopathic puerperal fever) may result from inoculation, from general or special idiopathic conditions, from decomposing placenta or secundines, or from putrid lochia.

Again, it is quite likely that for each of these general forms there may be sub-varieties, that in puerperal fever (contagious) we may have a catarrhal or diphtheritic specific action setting up vulvitis, vaginitis, metritis, etc., while in puerperal septicæmia there may or may not be endometritis, phlebitis, lymphangitis, emboli, multiple abscess, etc.

However, it is not the purpose of this article to go further into the morbid anatomy of these affections than is necessary to elucidate a distinct ætiological character for the two main classes as set forth.

But, if it is not yet sufficiently shown that the puerperal woman is subject, in the puerperal febrile maladies, to two essentially different diseases, then, as more conclusively establishing that fact, as more clearly exhibiting the action and its limitation of the poison of contagious puerperal fever, as establishing for this poison a specific principle, which attacks the woman from without, and as showing that the destruction of this contagium, or its exclusion from the mucous membrane of the genital tract, prevents the development of this fever in her, notwithstanding, as a result of the parturient act, local inflammations from lacerations and bruising have occurred, and as inferentially, but with equal force, arguing an entirely different ætiology for puerperal septicæmia (idiopathic puerperal fever), I would recall attention to the admirable work, and its most significant results, done by Dr. Henry J. Garrigues, at the New York Maternity Hospital, as set forth by him in a paper, entitled "Prevention of Puerperal Infection," published in the New York "Medical Record" of December 29, 1883.

For the purpose of better appreciating the results attained by Dr. Garrigues, and for the benefit of those who do not know already, it is well to state that the "New York Maternity Hospital does not exist at all except in so far that it has a medical board of its own, being in other respects only a department of Charity Hospital," consisting of three large wards and one small ward and a delivery-

room, set apart in that institution, a large general hospital in which all diseases, medical and surgical, are treated.

As set forth in that paper, the aggregate number of women confined in that institution from the beginning of the year 1875 to the close of the year 1882 was 3,027, with an aggregate number of 116 deaths, the percentages of death for the different years varying, being 2·67 for 1875, when it was lowest, and 6·67 for 1877, when it was highest.

During the first nine months of the year 1883, 345 women were delivered, of whom 30 died, 11 of these deaths occurring in Dr. Garrigues's service. The doctor states, also, that during his six months of service in 1882, or from October 1, 1882, to March 31, 1883, 192 women were delivered, of whom 46, or 1 in 4, were seriously sick, and 39, or almost 1 in 5, of inflammatory puerperal diseases.

When he went on duty, October 1, 1882, he says: "The condition of the hospital was at its worst, nine women having died during the last month, and half a dozen seriously sick puerperæ being left over, one of whom succumbed a few days later."

With this history of the service to consider, with the results of his own experience in the institution since his connection with it in his mind, and with the immediate not promising but "worst" prospect before him, the doctor began the service referred to by instituting a thoroughly antiseptic condition for his wards and all the necessary appurtenances they contained, and an antiseptic regimen for the service as regarded himself, his assistants, and nurses.

The results of the measures put into force are best given in the doctor's own language. He says: "The effects of the described treatment have been wonderful. As by magic all trouble disappeared. Ninety-seven women have been delivered since its introduction, and not only have *none of them died*, but there has *scarcely been any disease* among them, and especially no trace of diphtheritic inflammation, by which we used to be so persecuted. Up to this day we have had only six sick women; two had local perimetritic inflammation, three had metritis, and one had eclampsia. None of them, with the exception of the latter, have been seriously ill, and yet we have had two cases of podalic version and a craniotomy. Of the six patients, three only had a rise of temperature; the eclampsia case had none, and two of the patients with inflammation had none; and yet the presence of inflammation was sure enough proved by the symptoms—spontaneous pain, sensitiveness to pressure, and exudation. This *lack of fever* (italics mine) I can only explain by the perfectly aseptic condition in which the genitals were kept by the dressing, and in this respect it seems that our results are better than those observed elsewhere."

While for the details of the measures taken I shall refer the reader to Dr. Garrigues's paper (*l. c.*), yet I may say of them here that they included the strictest antiseptic precautions for each labor as it occurred in its turn. The special precautions taken and measures adopted—besides securing disinfection of the rooms, medical staff, nurses, and all instruments and utensils used—were (1) the use of intra-vaginal injections before and during labor; (2) the applica-

tion of a "pad," or an external antiseptic dressing for the genitals after labor; and (3), although not generally practiced, yet where the fingers or hand had been introduced into the womb, or instruments had been employed, prophylactic intra-uterine injections.

The external protective dressing for the genitals was renewed three times daily, or oftener as needed, the object being to guard the generative tract, at its orifice, against the entrance of an infecting poison, and also to prevent an attack of the poison at the orifice itself.

All instruments used, and cottons and lint employed, were also rendered aseptic by soaking or washings.

The results attained by these measures in their bearing upon the questions herein considered, as to the nature and ætiology of puerperal fever, are of marked significance.

While, however, it is not strictly relevant to the main questions herein considered to inquire to which of the measures employed by Dr. Garrigues the credit of the results attained should be given, or to determine whether they were due to the frequent emptying and fumigating of the wards which was practiced, to the strict antiseptic regimen which was enforced, to the intra-vaginal injections given preceding and during labor, or to the external genital dressing, yet, that we may not hereafter unwarrantably or unduly estimate either procedure, and thus be led to place too great reliance upon it, we may briefly, perhaps profitably, consider such inquiry.

There are strong reasons for thinking that to the repeated emptying of the wards, *their fumigation, antiseptic scrubbing, and subsequent exposure to the open air day and night for a varying time*, rather than to any other or all other measures, those results were due.

The efficacy of a thorough fumigation of a ward with burning sulphur, afterward allowing it to stand empty, with the windows open day and night for several days, as a preventive of puerperal fever, has been repeatedly shown—I may say proved—at Bellevue Hospital, both in its old lying-in wards in the north wing, and, more recently, in the Emergency Lying-in Hospital, a building connected with that hospital and attended by its regular house staff, although situated a block away in Twenty-sixth Street.

Such fumigation is not only deemed an *efficient protection* against subsequently occurring puerperal fever for a varying but for a *considerable* time by the members of the house staff, but is so considered by one of the visiting staff, who told me that, if over-crowding were not practiced—especially in the Emergency Lying-in Hospital—and if no puerperal fever case were admitted there, bringing contagion from without, the disease, subsequent to fumigation, would probably not reappear. On the other hand, he said, if over-crowding is compelled and practiced, then, in time, malarial troubles arise, fever occurs, and finally puerperal fever (contagious and peritoneal) is developed.

This statement, based upon observations most favorable for an inductive judgment, aside from its importance in regard to the *efficiency of fumigations as a preventive measure*—which is strongly affirmed—is *very interesting as showing the possible steps in the pathogeny of the puerperal fever, contagious*.

The value of the measure adopted second in order by Dr. Garrigues—of rendering the persons of the medical attendants, the nurses, and of others who might have duties therein, aseptic, on every occasion whenever they are to enter the lying-in wards or approach the parturient woman, as a means of prevention—can not in and by itself be properly estimated in a ward which has been fumigated, as, if the single measure of fumigation destroys the poison, and the doctor, or nurses, or others, who may get entrance to the wards, have not been exposed to other sources of puerperal fever contagion, they will not have the poison about them to communicate, and therefore aseptic preparation experimentally demonstrates nothing. But that the measure is not essential where fumigation has been carried out is evident by reference, again, to the service at the Bellevue Emergency Lying-in Hospital, where the house physician in charge passes from his general service in Bellevue to his obstetric service in the Emergency, without making the least aseptic preparation; and yet it is evident that puerperal fever is not generated by such neglect.

The value of the third measure—intra-vaginal injections before and during labor, declared by Dr. Garrigues, in a paper published in the March 1st number of this "Journal," as forming "a link of absolute necessity in antiseptic midwifery"—is equally far from being fully determined. As used, its merits can not be said to have been tested any more than the measure, just examined, of personal antiseptis. General experience teaches that the measure is unnecessary where infection is not endemically present, therefore it is probably quite as unnecessary where fumigation has been employed previously.

Until further evidence is adduced showing its value, Dr. Garrigues's claim for it—as a measure of necessity in antiseptic midwifery—is merely hypothetical.

As to the part accomplished by the external dressing for the genitals: While it fulfills a reasonable indication, and may be most valuable, yet the test as yet made of such value has, so far as I know, not been crucial or decisive. Had this dressing been used in the wards of Maternity prior to fumigation, and attended by the same results, or by like results, as those recorded by Dr. Garrigues, then no doubt could have been entertained as to its value. As it is, however, our judgment of it as a safe preventive measure must remain, for the time, uncertain.

While, therefore, fumigation and ventilation may be resorted to in rooms or wards where the puerperal fever contagium is endemic from previous propagation and occupancy, and is so limited, with confidence that such procedure will prevent further infection, yet that either one or all of the other measures practiced by Dr. Garrigues will, of themselves, accomplish the same result, is at least uncertain; and reliance upon them would be most hazardous.

Where, however, the contagium of this malady is epidemic, due to a state of generally existing malaria of a specific character—if possibly it may so exist in a more extended locality—then two preventive indications are presented: (1) To destroy the poison in the room to be occupied for the lying-in—which may be easily met by fumigation; and (2) to prevent subsequent infection from the sur-

rounding atmosphere—which may be met with the external genital dressing, as recommended.

However, to return to Dr. Garrigues's experiment and its results. The fact of importance relative to the trial he made is that, under most favorable circumstances for its continuance, the fever was stamped out; and that this result was due to the measures instituted we may conclude from its permanency. Writing two months later—a paper published in this "Journal" March 1, 1884—Dr. Garrigues says: "This method . . . has now been used in one hundred and seventy-five confinements in Maternity Hospital, and in the same wards where we used to have constant trouble everything goes smoothly."

By the method practiced, the generating morbid element, the cause of infection and fever, had been destroyed or excluded from the woman (whether destroyed or excluded, or both, does not signify in this connection), and no fever occurred. Hence, puerperal fever being prevented, not being a possible occurrence under these circumstances, such result proves conclusively its exopathic origin, or that its special infection comes to the woman from without. Furthermore, as inflammatory conditions did occur in the generative tract in those cases, notwithstanding puerperal fever did not result, we may conclude that *the pathogenesis of this fever is independent of local inflammatory aids*; and, as it is quite probable that in these one hundred and seventy-five puerperæ there were the usual number and extent of lacerations and the average condition of lochia, we may further conclude that such pathogenesis progresses or develops, when it occurs, independently of these states.

Lastly, from the fact that puerperal fever generates a contagium which propagates its like indefinitely, and until destroyed, we may conclude it possesses specific qualities.

Further conclusions to be drawn from the study and observations of puerperal fever before and after aseptic precautions in Maternity Hospital verify previous deductions already set forth: (1) That its contagium is endemic, and may so persist; (2) that where it is endemic in a confined habitat it may be destroyed or rendered harmless; (3) that it is not generated idiopathically, is not essentially inherent in the individual puerperæ's state; that neither in the fibrinous condition of the blood, the post-parturient condition of the endometrium, the hypertrophic state of the histological elements of the womb, neither in conditions of the lochia, nor in all these conditions combined, of themselves, is there the adequate element to generate that malady. Furthermore, that study with its inductions demonstrates that puerperal fever does not result from simple absorption of the uterine contents—"of organic materials in a state of putrid decomposition, which, when brought into contact with an open wound, set up inflammation in it"—and also negatives the teaching that "puerperal fever is *indeed nothing else* than the infection of fresh wounds, *such as are found in every newly delivered woman*, with septic material."

Also, from the character of the (inflammatory) processes which were present in the cases of puerperal fever which occurred in Maternity Hospital prior to the antiseptic regimen—*catarrhal* and *diphtheritic* vulvitis, colpitis, and metritis—and their absence subsequently, we are forced to the

conclusion that infection by that malady travels through the mucous membrane of the generative tract, gaining an entrance at its outlet.

Again, from the fact that puerperal fever continued by repeated outbreaks, or in intermittent severity, in Maternity Hospital from the time that institution was opened to the date of Dr. Garrigues's aseptic trial, from the fact of its many reappearances in the lying-in wards of Bellevue Hospital until they were discontinued on that account, and from the fact of its occurrence in Emergency Hospital, we may conclude that the disease can be developed *de novo*, as already pointed out, in (an overcrowded) hospital lying-in atmosphere.

But whether it may be generated in a general hospital from such malaria as therein exists, nosocomial, arising from general emanations, from surgical erysipelas, and from cadaveric emanations, where there is no overcrowding of puerperæ, and only an occasional confinement case, so that a single woman confined in such hospital shall be endangered by it—while such genesis is not fully shown by any evidence known to the writer, yet it is a possible, and may be a probable, occurrence.

Having established a specific or semi-specific malarial character for the poison of puerperal fever, we must thereby recognize a limit of the genesis of the malady to such specific cause; hence a result occurring from a different cause, although its pathological ensemble is almost identically similar, can not be held to be the same. On the other hand, upon this ground of deduction, as well as from the facts, namely, that it is idiopathic, is not contagious, is never endemic, and is not necessarily initiated by an inflammatory, catarrhal, or diphtheritic action, we may conclude that puerperal septicæmia is not identical with, but is distinct from, puerperal fever.

This conclusion, however, does not preclude the possibility of the two morbid conditions and actions being present in any one and the same case. Contagious puerperal fever may take on a septicæmic or putrid complication; and a case of puerperal septicæmia is equally susceptible, from exposure to the necessary infection, to puerperal fever; and that the two diseases do concur in hospital lying-in cases is most likely.

What it is that imparts a specific character to the poison of puerperal fever—what constitutes the essence of such malaria, on the one hand, or what it is that determines a retained placenta, clots, secundines, or the lochia, under certain conditions and at times, to take on septic action, on the other, are interesting questions for study; but, from data at present available, they are not capable of a perfectly satisfactory solution.

Whether, as some hold, bacterial forms which gain a footing in the puerpera comprise the specific essential in either case is, so far, problematical.

While we can theoretically account for the occurrence both of contagious puerperal fever by ascribing it to one form of bacteria, and of puerperal septicæmia by ascribing it to another, yet, for the purposes of prevention, I do not see that anything is gained by such hypothesis. And the bacterial forms that have been found may, so far as clinical

results are concerned, and quite as well, be regarded as consequences rather than causes.

The general inferences from the foregoing are: 1. *That puerperal fever and puerperal septicæmia are essentially two distinct diseases.* 2. *That they both arise from blood poisoning through the predisposed generative tract, but the poisons which generate them are not the same.* 3. *That the puerperal woman in private practice is not especially liable to contract puerperal septicæmia, and that she only contracts puerperal fever from a specific malarial contagium.*

(To be continued.)

A CASE OF

ECCHONDROSIS OF THE LARYNX.*

By MORRIS J. ASCH, M.D.

CARTILAGINOUS tumors of the larynx are of such infrequent occurrence that possibly the report of a case may not prove uninteresting. There are very few cases of the kind on record. Froriep described a case of chondroma of the larynx where three large, partly ossified tumors sprang from the thyroid cartilage and considerably narrowed the laryngeal cavity.† He also cites a case from McIlwain, "Edin. Med. and Surg. Journal," 1831, which, however, is doubtful as to the diagnosis. Virchow describes rounded excrescences, springing from the cricoid, which become more and more pointed, and one case where the tumor arose from the anterior inner surface of the thyroid; here the excrescence was ossified, and formed a true exostosis, under which the mother cartilage was preserved intact. (Virchow, "Path. des tumeurs," vol. i, p. 442, Traduc. Ahronson.) The case of bronchial stenosis, the result of ecchondroma, reported by Gerhardt ("Jen. Zeitschrift für Med. u. Stat.," Band iii) can scarcely be considered a case of laryngeal growth. Mackenzie reports a case where a cartilaginous tumor, arising from the cricoid cartilage, extended downward in front of the trachea (Mackenzie on "Growths in the Larynx," p. 54). Musser (Path. Soc. of Phila., in "Phila. Med. Times," May 6, 1882) reports a case of ecchondroma of the larynx where a tumor of the size of a walnut grew from the posterior surface of the cricoid cartilage into the lumen of the larynx. The diagnosis here was made after death, the patient having died of pneumonia following tracheotomy. No microscopical examination is given in the report.

I find, however, but two cases reported where cartilaginous tumors of the larynx were diagnosed as such and treated during the lifetime of the patient. One case is recorded by Ehrendorfer ("Wiener med. Woch.," July 2, 1881), where the tumor grew from the back of the thyroid cartilage and made its way into the larynx by passing between the arytenoid cartilages. It was removed by Billroth by external incision, the nature of the growth having been ascertained by the removal of a piece during the operation of tracheotomy. The other case, the only one reported where the affection was treated by the endolaryngeal method, occurred in the practice of Stoerk ("Klinik der Krankheiten

* Read before the American Laryngological Association, May 13, 1884.

† R. Froriep, "Preuss. Vereinszeitung," 1834, No. 38.

des Kehlkopfes," p. 417), where the tumor sprang from the arytenoid cartilage. Particular interest attaches to such tumors from the fact that Virchow states (*op. cit.*) that, from their thickness and hardness, they can not be removed *per vias naturales*.

R. C., aged forty-two, presented himself to me a few months ago, complaining of constant irritation of the throat, attended by frequent hoarseness. He was an amateur vocalist of considerable merit, and insisted that there was something in his throat which prevented a complete development of his vocal powers. He had been under treatment for chronic laryngitis for a long time without result. A laryngoscopic examination showed a curious growth springing from the inner surface of the thyroid cartilage, apparently at the base of the superior cornu of the right side. It projected anteriorly and inward toward the base of the epiglottis for about five sixteenths of an inch. It was conical in shape, and covered by mucous membrane, which it pushed before it in a tent-like manner, and which, during certain movements of the throat, rose over the growth, com-

pletely hiding it. I had never seen such a growth, and was puzzled at first to make out its nature. Frequent examination, and touching it with the finger as well as the sound, convinced me, however, that I had to do with an echondrosis—a cartilaginous tumor springing from cartilage, as distinguished from an enchondroma where the cartilaginous tumor originates from bone or any substance other than cartilage (Virchow and Cornil and Ranvier)—in which opinion Dr. A. H. Smith, who saw the case in consultation, agreed. At first I was in doubt whether to attempt its removal by the endolaryngeal method, or by external incision, being influenced by Virchow's statement as to the hardness of these tumors, and I had not at the time read Stoerk's account of his case. However, as the tumor seemed to afford an excellent opportunity for attempting its removal by the mouth, and as the patient was exceedingly anxious to be rid of it, I determined upon this operation. The shape of the tumor indicated the guillotine as the instrument to be preferred. I accordingly had a very strong and sharp one made after Stoerk's pattern, having the ring of steel with a cutting edge on its upper border, the stem being bent to the left, so as to give greater facility in viewing and manipulating the growth. On the 15th of April last the patient presented himself for the operation, which I performed, assisted by Dr. C. H. Knight. At first it was extremely difficult to include the growth in the ring of the instrument. The patient was brave but nervous, and his larynx was in constant motion. On every attempt to seize the tumor the movable mucous membrane would rise and completely cover it, and it was only during phonation of certain sounds that I was able to see it satisfactorily. In making an attempt at section, I cut off a piece of the mucous membrane at its apex; through this the growth protruded, and at the next attempt the instrument encircled it to its base and the removal was effected without difficulty. There was no hemorrhage. There was a little pain in swallowing

for a few days, after which the throat was perfectly normal. The voice has improved, according to the patient's statement, to the extent of adding two notes to his register, which, I need scarcely say, affords him great satisfaction.

A microscopic examination was made by Dr. G. L. Peabody, Pathologist to the New York Hospital, who reports as follows, after examining several sections without finding any ossification:

Each of these sections consists of cartilage at its center, in many cases well preserved. There are large lumps of blood-pigment in the matrix, in the capsules, and occasionally in the cartilage-cells. Some of the sections show the "asbestos" degeneration of the matrix, and the further change of cells, etc., into lumps of calcareous material, into which carbonate of lime enters largely. By adding sulphuric acid I have decomposed this carbonate, and seen under the microscope the evolution of carbonic-acid gas in two sections. These forms of degeneration take place physiologically in the costal cartilages, and doubtless elsewhere, in advanced life.

Thus, gentlemen, I have described a case of cartilaginous tumor of the larynx undergoing calcareous degeneration—a case interesting for its rarity, and valuable as being a proof that such tumors come fairly within the province of the laryngoscopist, not merely for diagnosis, but for their cure by endolaryngeal methods.

DISCUSSION.

Dr. COHEN.—I have never seen a similar case, and but two or three specimens of echondrosis of the larynx are to be seen in the museums in Europe. With regard to recurrent laryngitis, there are some cases in which it is due to the influence of a growth outside of the larynx proper. It is somewhat peculiar that the removal of the tumor in Dr. Asch's case should have had the effect of increasing the resonant powers of the voice in so marked a degree.

Dr. SEILER suggested the explanation that the tumor had interfered with the resonant cavity above the vocal bands. It was not probable that the tumor could so interfere with the bands as to make a difference of two notes in the scale.

Dr. LANGMAID.—I think the reason for the increase in the vocal resonance very problematical. It seems strange, as Dr. Cohen has suggested, that anything outside of the muscular apparatus should interfere with the tone, or that its removal should increase the scale. It is possible that the so-called moral effect of removal of the obstacle may have had something to do with encouraging the voice to act. I should not like to deny Dr. Seiler's proposition, but should rather think the two facts combined—namely, the removal of the laryngeal irritation, and the moral encouragement given by removal of the obstacle—would account for the increase in the scale.

Dr. ASCH was inclined to accept Dr. Langmaid's explanation of the change in the voice.

The Health of Paris.—According to the statement made by the Director-General of Public Assistance at Paris, no cases of true cholera have been observed in hospital, although diarrhoea is frequent enough. Some fatal cases of cholera nostras have occurred in the town, but, as they are really limited, and do not spread, they may be referred to the ordinary state of public health during the summer months in Paris. It is well-known, of course, that every year, in July and August, some cases of sporadic cholera break out in this city.—*Medical Times and Gazette*.

CAN LOCOMOTOR ATAXIA BE CURED?*

By GRÆME M. HAMMOND, M.D.,

LECTURER ON ELECTRO-THERAPEUTICS AT THE POST-GRADUATE MEDICAL SCHOOL.

A FEW years ago, when a member of the medical profession announced that he had cured a case of locomotor ataxia, his statement was not received with a great amount of interest. Belief in his views was not entertained for a moment. It was absurd even to talk about curing ataxia, and it was thought that the physician had made an incorrect diagnosis, or else that an intermission of the disease had occurred at an opportune moment. The pathological condition found existing in the spinal cord in persons who died while suffering from this disease seemed to warrant the views held by the majority of physicians that a cure of ataxia and all similar affections, such as the sclerosis of the different parts of the cord and brain, was an impossibility; but, as time has passed, reports of cases cured have come before the profession, many of them reported by men of such undoubted learning and high reputation that we can not afford to overlook them. The question, therefore, that arises is, Are these true cases of ataxia, or is there some other morbid condition of the spinal cord which, when present, gives rise to symptoms similar in every respect to those resulting from sclerosis of the posterior columns? I have been enabled to collect a few cases of undoubted cure of what was supposed to be locomotor ataxia, and I think their histories, and the different methods of treatment employed, go far to settle the question of the curability of posterior spinal sclerosis.

CASE I.—The patient, whom I am fortunately able to present before you for the second time, was the subject of a short paper read before this society last June. I then exhibited him as a case of locomotor ataxia cured, and, I am happy to say, the cure has so far stood the test of time.

His history is as follows: Ten years ago he came under the observation of Dr. James Anderson, of this city, for a lesion of the glans penis. Dr. Anderson is unable to say at this date whether it was a chancre or a chancroid. No secondary symptoms were ever apparent. He has two children, both of whom are perfectly healthy. He had been a drinker for several years, seldom going on a spree or becoming intoxicated, but taking a good many drinks every day. In the winter of 1882 he went on a spree, which culminated in an attack of delirium tremens. Following this attack, the prominent symptoms of ataxia appeared, though for the previous six months he had complained of sharp, shooting pains in the legs, and slight difficulty in walking. He was now unable to stand without support. When assisted, his walk was characteristic of ataxia; there was a loss of the tendon reflex, a difficulty in retaining the urine, and anæsthesia of the lower limbs. The arms were somewhat affected, and there was partial loss of sight.

Dr. Anderson prescribed iodide of potassium and bichloride of mercury, and referred him to me for further treatment. I applied the actual cautery several times to the spine, together with dry cups, the ether spray, and static and galvanic electricity. From this time the patient began to improve, and, when I exhibited him before you one year ago, he was apparently per-

fectly well. He walked correctly, could stand with his eyes closed, and jump on and off a car while it was in motion. The tendon reflex returned. On this latter point he was tested by several members of the society. He has had no treatment whatever since then. He takes no wine or liquor in any form. He is stouter, and seems to be in better condition now than he has been any time for several years. During the past winter he frequently ran over the ice and snow, drawing one of his children on a sled—a feat which any person afflicted with ataxia would find it impossible to accomplish.

CASE II.—Desplat (of Lille), in "*L'Union médicale*," Nov. 29, 1883, reports the case of a man, fifty-four years of age, who had contracted syphilis twenty years previously. For the past five years he had shown symptoms of locomotor ataxia—such as plantar anæsthesia, loss of the idea of the exact position of the limbs, partial anæsthesia of the upper limbs, absence of the tendon reflex, and incoordination. He was treated with Gibert's syrup and mercurial frictions. In five days an amelioration of the symptoms was observed, and in five months the cure was complete.

CASE III.—A gentleman from Peekskill, N. Y., consulted Dr. William A. Hammond about two years ago. He exhibited all the symptoms of locomotor ataxia. He was unable to stand with the eyes closed; the tendon reflex was absent; he was unable to hold his urine for any length of time, having to pass it as often as forty-five times a day; anæsthesia was present; and the passage of sensory impressions through the cord was considerably prolonged. A specific history was admitted. Dr. Hammond treated him with iodide of potassium and bichloride of mercury, alternating occasionally with nitrate of silver. The actual cautery was applied to the spine, together with dry cups, ether spray, and galvanism. Improvement in his symptoms was gradual, but steady; the anæsthesia disappeared, he began to stand and walk better, and his urinary symptoms improved, but the tendon reflex did not return.

Not having seen him for nearly a year, I wrote to him on May 21st. Two days later I received a letter containing the following statements: "Dear Doctor.—In reply to yours of the 21st, it affords me great pleasure to state that I have not enjoyed such good health in years, and, as far as I am able to judge, *completely cured of locomotor ataxia*. I have no difficulty in walking or standing in any position, and feel equal to any physical exertion. As to my bladder, I hardly know I have one."

CASE IV.—Dr. Friedrich Schultz, of Heidelberg, in a paper entitled "*Zur Frage von der Heilbarkeit der Tabes*," which appeared in the "*Archiv für Psychiatrie und Nervenkrankheiten*," Berlin, 1881, Band xii, relates a most remarkable case. The patient, in April, 1871, was first seen by Erb. He was then forty-three years of age, and had been suffering for two or three years with lacerating pains in the lower extremities. For a year he had been unsteady on his legs, and had suffered from an inability to retain his urine. These symptoms gradually became worse. He was unable to walk in the dark, was totally unable to retain his urine at night, and could only do so during the day for a short time by making great efforts.

Under the use of nitrate of silver the latter trouble was somewhat improved, and he became able to stand better with his eyes closed. From the middle of April, 1871, the galvanic current was used, the patient continuing to improve in his powers of locomotion until the eye could hardly perceive any abnormality in his gait.

All of the symptoms gradually disappeared, until, in 1873, about two years after treatment began, he was considered to be perfectly well.

He remained well up to the time of his death, which occurred suddenly during an attack of acute intoxication. Just

* Read before the American Neurological Association, June 20, 1884.

previous to his death Dr. Schultz saw him, and noted the following facts: "The gait was perfectly normal, sensibility intact; the patellar tendon reflex on both sides was perfect; slight enuresis both at night and through the day."

Nine hours after death an autopsy was held. The spinal cord was found to be small and soft. Diffuse degeneration of the posterior columns in the lumbar region existed, together with degeneration of the outer division of the posterior columns of the dorsal region, and slight degeneration in the column of Goll.

I think this is a most instructive case. How it is possible for sclerosis of the posterior columns to exist without the manifestation of any symptom of ataxia, except a slight enuresis, can only be accounted for in one way. In such a case we are forced to conclude that some other condition of the cord, co-existing with or occurring separately from the sclerosis, is capable of producing a majority if not all of the symptoms of ataxia, and that this morbid state, under certain conditions, is capable of being removed by appropriate treatment. In support of this view let me quote the following cases:

CASE V.—Desnos, at the Société médicale des Hôpitaux, July 13, 1883, related the history of a characteristic case of ataxia which ended fatally. Cadiat, who made the autopsy, found the cord to be very intensely congested, but could not discover the slightest evidence of sclerosis of the posterior columns, or, in fact, of any part of the cord.

CASE VI.—Another case, reported by the same authority, refers to a man twenty-four years of age, who had contracted syphilis several years before. He was also exhausted by sexual excesses and literary pursuits. Desnos, after making a diagnosis of ataxia, prescribed five centigrammes of the proto-iodide of mercury, from four to five grammes of iodide of potassium, and four grammes of bromide of potassium every day. This treatment was interrupted several times on account of its causing gastric disturbances, but at the end of five weeks the patient showed considerable improvement. Shortly after the patient was regarded as completely cured. Desnos regarded this also as a case of congestion.

CASE VII.—Dr. Henry Lyman, in the "Chicago Medical Journal and Examiner," January, 1883, reports a very interesting case. The patient consulted him in 1879. He was then suffering from lightning-like pains in the legs, anesthesia, paræsthesia, and analgesic patches on the limbs. The tendon reflex was absent, the ataxic gait was well marked, there was loss of co-ordination in the upper extremities, inequality of the pupils, and choked disc. The treatment at first consisted of ergot, nitrate of silver, and galvanism. The patient did not improve. On a visit to New York he consulted Dr. Seguin and Dr. Beard, both of whom confirmed the diagnosis of ataxia. He continued using nitrate of silver and galvanism, together with iodide of potassium and bichloride of mercury. In January, 1881, some of his friends advised him to use Junod's boot. He did so, and, after a month's trial, the pains in his legs began to disappear. He then procured some dry cups, which he applied to both sides of the spine, still continuing the use of Junod's boot to both legs. In the summer of 1881 all pain ceased, the rectum regained its power, the eyesight improved, and the sphincters of the bladder were restored to their normal state. Some time later, when Dr. Lyman examined him, he found there was still some slight degree of ataxia in the movements of the feet, the upper extremities were perfectly manageable, the anesthesia had disappeared, but the tendon reflex had not returned. The patient walked well and rapidly without a cane.

The first case mentioned in this paper is certainly a complete cure, and, with a single exception (the case reported by Dr. Schultz), is the only one in which the tendon reflex has been restored. The third case, the patient residing in Peekskill, and who was under the care of Dr. W. A. Hammond, is a complete cure, except that the tendon reflex has never been re-established. This is no evidence that he is not entirely well. It is a well-known fact that a few persons never have had any knee reflex, and it is barely possible that this may be the case with him. If it is not so, it is conclusive proof that some morbid pathological condition still exists in the spinal cord. It may be sclerosis, or it may be congestion; no one can tell. It has just been shown in Dr. Schultz's case that sclerosis existed in both the lumbar and dorsal regions, and yet the patellar tendon reflex was present in both legs. We must therefore conclude that the deep reflexes are not always, if ever, transmitted, as is commonly supposed, through the posterior columns, but sometimes at least pass through the posterior horns of gray matter. It would in that case be impossible to tell whether the symptoms were caused by a lesion in the posterior columns or in the posterior horns of gray matter. The case reported by Desnos, in which the autopsy was made by Cadiat, showed that all the symptoms were due to congestion, and it would seem as if the symptoms in Schultz's case must also be attributed to the same cause. They certainly were not dependent upon the sclerosis. Lyman's case, which was so much improved by dry cupping to the spine and Junod's boot, was undoubtedly relieved by the dissipation of the congestion in the cord.

From a study of these cases, I have arrived at the following conclusions:

1. That the absence of the patellar tendon reflex in locomotor ataxia is not always caused by sclerosis of the posterior columns.
2. That sclerosis of the posterior columns may exist without being accompanied by the ordinarily prominent symptoms of ataxia.
3. That congestion of the posterior half of the spinal cord may give rise to most, if not all, of the symptoms of locomotor ataxia.
4. That it is impossible during life to make a differential diagnosis between posterior spinal sclerosis and posterior spinal congestion.
5. That posterior spinal congestion is curable.
6. That there is no evidence to show that sclerosis once existing in the spinal cord has ever been removed.
7. That those cases of so-called locomotor ataxia which have been cured are simply cases of spinal congestion more profound in the posterior half of the cord.

Contagious Pleuro-pneumonia among Cattle in the West.—A serious outbreak has taken place among Jersey cattle in Illinois, and Dr. Salmon, of the Bureau of Animal Industry, who has investigated the matter, has reported that there is no doubt as to the nature of the disease. He also expresses the fear that the infection has been extensively diffused, since many of the cattle were widely distributed as the result of a sale. It is stated that the most energetic measures will be taken, both by the national authorities and by those of the State, to limit the progress of the disease so far as possible.

Book Notices.

The Pathology, Diagnosis, and Treatment of Diseases of the Rectum and Anus. By CHARLES B. KELSEY, M. D., Surgeon to St. Paul's Infirmary for Diseases of the Rectum, etc. With two chromo-lithographs and nearly one hundred illustrations. New York: William Wood & Co., 1884. Pp. xiii-416.

This excellent work, while it has for its basis the volume on the same subject contributed by the author to "Wood's Library of Standard Medical Authors" in 1883, contains an entirely new chapter of thirty pages on Rectal Hernia. Many changes have also been made, chiefly of such a practical character as would be suggested by the daily practice of the specialty. The author's style is conspicuous for clearness and aptness, and his quotations are terse and to the point. The latter makes a virtue of what might well have become a fault in a book which makes such frequent allusions to other works.

A prominent feature is the large number of excellent illustrations to relieve the text of many long descriptions which would otherwise be necessary. To the practicing physician it is of the greatest importance to have for reference a book which faithfully depicts the measures of treatment that are still in vogue, and does not contain long passages referring to treatment which has become obsolete. In this regard Dr. Kelsey's work can not fail to give satisfaction. It clearly describes the methods of treatment which are to-day approved of by the best authorities, and seldom fails to give the reader definite ideas and plans upon which he can act at once.

Correspondence.

LETTER FROM WASHINGTON.

The late Surgeon Woodward.—Congressional Items.—Measures for the Suppression of Traveling Quacks.—Dr. Fisher, of the Marine-Hospital Service.—Vital Statistics and the Census. The Washington Chemical Society.

WASHINGTON, August 26, 1884.

Or that remarkable trio who have made the Medical Department of our army famous throughout the world, only Dr. Billings remains. His splendid physique has hitherto preserved him from the consequences of the intense application which proved fatal both to Otis and to Woodward. We hear occasionally that such and such a one will be assigned to fill the place of Woodward. Nobody can fill such a place; both Otis and Woodward were *sui generis*; they were made such partly from the original bent of their minds and partly from their surroundings; but, in the absence of original adaptability, no outcome such as we have seen could be produced through any combination of circumstances. Hence those are likely to be doomed to disappointment who conclude that the official order is all that is needed to find a man to complete the third volume of the "Medical and Surgical History of the War of the Rebellion."

Expertness in chemistry, microscopy, and pathology may indeed be found, but the volume will lack the varied and ripe experience that Woodward's twenty years of application in that particular field alone could give.

The laws of the last session of Congress, now published, contain many things of professional interest not heretofore noticed in your columns, among them the law providing for the publication of the reports of the Bureau of Animal Industry, of which Dr. Salmon is the chief, and the establishment of the precedent for pensions to female nurses during the late war. (An Act for the relief of Maria L. Hammer, private No. 81.)

The Medical Society of the District of Columbia, at one of its recent meetings, appointed a committee to inquire what action might lawfully be taken against the unusual number of traveling quacks that frequented the city during the past winter, owing, no doubt, to the fact that so many of the States have adopted stringent laws concerning them. The committee, after an examination of the subject and consultation with the district attorney, reported that it was unlawful for any person to practice medicine or surgery in the district without a license from the medical society. It was then ordered that any member having knowledge of a person practicing without authority should report the fact to the corresponding secretary. It was made the duty of that officer to notify the accused to appear before the board of examiners and make application for license. It appears there is a penalty of fifty dollars attached to a violation of the law, one half of which, when collected, goes to the informer. No convictions have yet been had, but it is presumed that a knowledge of their liability may induce the wandering quacks to seek "pastures new."

The many friends in this city of Dr. John C. Fisher, of the Marine-Hospital Service, have been not a little surprised to learn of his resignation. It appears that he goes to Beirut, Syria, to become connected with the medical college and hospital at that place, which is conducted under the auspices of the American Protestant Missionary Society. If the doctor will furnish as entertaining reports from Syria as Dr. Stuart Eldridge (Georgetown, 1868) has from Japan, medical literature will be greatly the gainer.

The Report on Vital Statistics by the United States Census Bureau is completed but not yet issued. The plan of this part of the census is the work of Dr. Billings, and will doubtless embody his well-known views on registration. The value of statistics gathered from every village and hamlet in the United States will necessarily be great. Ordinarily, the published health statistics are from cities only, the rural population and mortality being left out of the account, but for this work every physician, regular as well as nondescript, city and country, was requested to make a return of the mortality occurring in his practice during the year. A blank-book was furnished and return postage given. As the returns of the physicians were made to tally with those of the enumerators, the percentage of error is probably very slight. It is a pity that this branch of the census can not be made a permanent organization, with annual reports instead of a volume covering only a single year out of the ten.

The Washington Chemical Society was recently organized. There are few cities where such a society can have so many active workers. The Patent Office, the Smithsonian Institution, the National Museum, the Mint Bureau, the Agricultural Department, the Geological Survey, as well as the various medical bureaus of the Government, employ chemists, and some very bright ones at that, so that the capital is in no wise behind in the study of general science.

A school of technology has recently been begun in connection with the Columbian University.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & CO.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, AUGUST 30, 1884.

THE WASHINGTON MEETING OF THE INTERNATIONAL
MEDICAL CONGRESS.

Now that it seems to have been definitely settled that the next International Medical Congress is to be held in this country, it behooves the entire medical profession in the United States to do its best to secure a successful meeting. The invitation, it is true, was formally authorized by the American Medical Association, and it was in every way proper that that should be the case; but it will take more than the resources at the command of the association to assure the full measure of success to which we may reasonably aspire. If we understand the matter aright, Dr. Billings, of the army, who, as the chairman of the association's committee, conveyed the official invitation, is in a position to exercise a controlling action with regard to the general outline of the arrangements, and without being strictly bound down to the employment of the association's machinery. That is to say, in the constitution of his subcommittees he is at liberty to seek after the men that may seem to him the best for the purpose, although they may not be prominent in the association or even connected with it in any way. In short, the work is not to rest solely upon the shoulders of any organization now in existence—not even of so broad an organization as the American Medical Association. And we think this state of things is fortunate, for, as we hinted at the outset, it will tax the strength of the profession, as a whole, to make a showing at all fit to be compared with what was seen in London or with what has recently been seen in Copenhagen.

In the matter of entertainments—and, say what we may, that phase of the undertaking will be uppermost in many men's minds—we can not hope to equal the capital of the richest empire in christendom, and we shall be fortunate if we can come up to that of the little kingdom in which a meeting has just been held. The pomp of royalty is unknown among us, and we have not so much as a Lord Mayor to fall back upon. The time may have passed when any considerable sincerity could attach to our pretensions to a simple mode of life, but whatever lavishness there is among us is not likely to creep out into view to any great extent in the overcrowded ranks of the medical profession. Our nabobs have no particular interest in medicine, and the officers of our National Government, whatever their willingness may be, have nothing but their private means to draw on for purposes of hospitality. Under those circumstances, we think it would be perfectly proper for Congress to make a handsome appropriation to cover the expense necessarily involved in entertaining our visitors on a scale approaching that which our importance as a nation certainly calls for. But, that resource failing, good feeling may be shown in a

tent as unmistakably and quite as effectively as in a palace, and, although we may not make much of an impression on that one of our London contemporaries which has already taken occasion to remark that now the Americans would have a chance to show what they could do, there is no reason to doubt that we shall be able to make our visitors comfortable. For the rest, so far as the social element is concerned, we must trust to their good nature.

The matter of hospitality, however, is not the most puzzling with which we shall have to deal; the intellectual vitiating will try us more. In view of our isolated situation, it is hardly to be supposed that we can count on so large an attendance from foreign countries as the smallest European State could; it will therefore occur to us that we must furnish more of the scientific matter ourselves than would otherwise be expected of us, and yet we must not overdo the thing. Just where to draw the line between a barren dearth and a surfeit will be the delicate question. We may well imagine that there will be no lack in quantity, but the rub will come in connection with the matter of quality. Much will depend, in this respect, upon the make-up of the auxiliary committees, and it is to Dr. Billings's rare penetration and discretion in such affairs that we look in entire trustfulness.

On the whole, then, while it would be unwise for us to try to make a show of pageantry, the angury seems good for a satisfactory meeting, but the three years that are to elapse are none too long a time in which to make our preparations.

THE ARMY WORM AND THE CHOLERA FUNGUS.

In its early history, and, indeed, up to a comparatively recent period, medicine, in common with other fields of scientific inquiry, was beset with theories—fairly overgrown with them, as a tender plant may be well-nigh choked with worthless weeds. This clog upon its progress it had to endure much longer than almost any other branch of science, and the reason of its prolonged bondage it is not difficult to comprehend. Dealing constantly with the unlearned, and dependent on their favor for their daily bread, its practitioners have always felt, and for a long time to come, it is to be feared, must continue to feel, the pressing necessity of keeping up a close approach to the omniscience which the popular demand assumes that they ought to possess. Such a pose can be maintained only by a bearing quite the reverse of the scientific attitude. He who says "I don't know" is like him who hesitates—lost. The man of science asserts nothing until he thinks it is proved; the man of the people—and a doctor must be that to achieve material success—gives loose rein to his fertility of resource, and is ready to assert anything plausible, provided he has no reason to think that his interlocutor is capable of disproving it. Thus it happens that men who must every day thrust their tongues into their cheeks, like the augurs of old, to keep themselves from laughing, are tempted by the force of habit to carry this acquired facility of theorizing into their intercourse with their fellow-workers and into their own serious thoughts. Under a particular set of circumstances they are, indeed, quite prone to

yield to the temptation, namely, when they find themselves literally on the witness-stand in a court of justice. But it is one of the greatest virtues of physicians that, with that single exception, their studied ingenuity is resolutely cast off when they find themselves face to face with the real problems of nature; there is no more sturdy agnostic than the medical investigator.

This sort of self-discipline has come to be recognized as the touch-stone by which the scientific *afflatus*, so to speak, is to be recognized. Has it not been carried too far? Is it not mainly responsible for the "therapeutic nihilism," to use Professor Bartholow's happy phrase, that, having answered its purpose, has become effete, and must be cleared away as rubbish? We do not doubt it. Not that we could afford, in the interest of our art, to lapse into the easy-going ways of the old "authorities"; but it does seem that we ought to halt somewhere between that point and the sway of the dictum that would limit the working of man's mind to that of a recording instrument—that commands him to rest content, when he hears the voice of nature, to play the part of a phonograph.

Elsewhere in this issue of the journal we publish what seems to us a shining exemplar of the justness of our view, in the form of an abstract of a remarkable paper read before the Chicago Medical Society by Dr. John Bartlett—a paper which we look upon as substantiating the occasional utility of even a degree of daring in the matter of theory, if only, to use Dr. Bartlett's words, "as a framework which might hold together in an apparently perfect order and relation a large number of fragmentary facts that might be lost sight of if allowed to lie detached and disconnected." In a note which accompanied the manuscript report of the meeting, the secretary of the society, Dr. Montgomery, says: "The illustrations made use of, the army worm and the marsh fungus, have been carefully studied in the field by the author. He was the first writer on the army worm—as early as the year 1861 he wrote a long article. His experience with the cholera has also been ample." We can readily imagine that it was not until after abundant study that Dr. Bartlett was enabled to display such a masterpiece of analogy as that in which he traces the probable points of resemblance between the migrations of the worm in question and those of the cryptogam, whatever it may be, that gives rise to the cholera. It seems to us that an analogy of such complexity, and yet of such strict compatibility with known facts, while it reflects the highest credit on its author, can not but be of service in the study of the etiology of cholera, and we are quite prepared to see the army worm turn out to have thus made some amends for its ruinous existence.

THE COMMA BACILLUS.

ALTHOUGH the bacillus of tuberculosis can scarcely yet be said to be beyond the need of Dr. Koch's parental protection, so to speak, he seems amply prepared to do battle for the deadly comma bacillus. While it is true that Dr. Strauss and Dr. Roux, among Pasteur's followers, are still positive that the comma bacillus has been found associated with other diseases

than cholera, and while it is urged as an objection to Koch's views that inoculations of the lower animals with the comma bacillus have not yet succeeded in communicating cholera to them, Koch boldly declares himself perfectly satisfied that his bacillus is the cause of cholera; and it must be confessed that, thus far, he seems to have the best of the dispute.

So far as we have noticed, Strauss and Roux have not been very explicit in their statements as to what other diseases than cholera are associated with the presence of the comma bacillus, and it is possible that they may have been deceived by a micro-organism, said to have been observed in India, which is described as indistinguishable from the comma bacillus except by its being somewhat thicker, and by its being destitute of the property of liquefying gelatin. The slight difference in thickness may well have escaped observation, and we have no information that the organism was subjected to the gelatin test in the cases alluded to.

In regard to the objection that all attempts to convey cholera to the lower animals by inoculating them with the bacillus have failed, Koch does not, so far as we have observed, assert without reserve that the lower animals are proof against the disease, but he certainly adduces a number of facts which can only be interpreted as showing that that is the case. Among others, it seems that diligent inquiry brought out the fact that the disease had never been known to attack the lower animals in a certain district of India where it was always, and had been from time immemorial, prevalent among human beings. If we concede the immunity of the lower animals, this fact, as Koch remarks, ought not to be held as invalidating the position that the bacillus gives rise to the disease, for, as he correctly observes, various parasites have their particular "hosts," and will gain a foothold in none others—different animals, for instance, constituting the exclusive abode of so many separate varieties of tape-worm. It has been made to appear, however, that, under certain circumstances, choleraic dejecta do exert a most pernicious effect upon swine, alone of all the animals on which they have been tried (for Thiersch's results in experiments on white mice Koch has not succeeded in producing); but, yet, cholera has not been given even to swine.

This evil effect on hogs seems to throw some light on the *modus operandi* of the cholera bacillus. It does not kill by direct infection of the blood, for it does not enter that fluid; indeed, it seems to flourish nowhere except in the lower part of the ileum, and is seldom ejected with the vomited matter, and then, as Koch thinks, only when there is fecal vomiting. Its peculiar pathogenetic power, therefore, may be connected with its capability of giving rise to the production of poisonous material, like the power of some of the bacteria to give rise to septicæmia in the same indirect way.

The comma bacillus seems to be easily killed, or at least deprived of its power for harm, desiccation being sufficient for that purpose; hence Koch concludes that cholera is never transported in merchandise, and seldom if ever by the wind, but only by human intercourse. The whole history of cholera outbreaks confirms this view, and the supposed local origin

of certain epidemics appears to have been pretty thoroughly disproved.

According to Koch, the bacillus can not be supposed to be a product of the cholera, for there are no facts to show that any disease can create a living organism; and it is highly improbable that it is some ordinary bacterium transformed by the disease, for no analogous transformation has been witnessed. The bacillus is peculiar to the human subject, and is never met with except in the intestine of man, or in media that may reasonably be supposed to have derived it from human excreta.

The practical bearing of Koch's discovery lies chiefly in its enabling us to make a positive diagnosis in doubtful cases, and to avoid loss of time in taking measures to prevent the spread of the disease.

MINOR PARAGRAPHS.

THE "POISON" LABEL IN PHILADELPHIA.

A MEETING representing the medical profession and the drug trade of Philadelphia has been held to take action upon the case, alluded to in our last issue, in which a deputy-coroner held a dispensing clerk responsible for omitting to affix the "poison" label to a box of strychnine pills, a young woman having lost her life as the result of swallowing a number of the pills. At the meeting much indignation was expressed at the conduct of the deputy-coroner, and many of those present declared positively that they would not conform to that official's interpretation of the law bearing upon the matter. The law reads as follows:

No apothecary, druggist, or other person shall sell or dispose of by retail any morphia, strychnia, arsenic, prussic acid, or corrosive sublimate, except upon the prescription of a physician, or on the personal application of some respectable inhabitant of full age of the town or place in which such sale shall be made; and in all cases of such sale the word "poison" shall be carefully and legibly marked or placed upon the label, package, bottle, or other vessel in which such poison is contained.

The deputy-coroner's construction of the law was held to be negative by the comma before and after the clause "except upon the prescription of a physician." That will do if it is sustained by the courts, but it seems to us that there are more solid grounds for disputing the deputy-coroner's interpretation.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending August 26, 1884:

DISEASES.	Week ending Aug. 19.		Week ending Aug. 26.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	2	1	0	0
Typhoid Fever.....	36	9	26	14
Scarlet Fever.....	30	4	32	6
Cerebro-spinal meningitis. . .	1	1	2	2
Measles	43	6	47	11
Diphtheria	22	14	22	11

Cholera.—The situation in France has not changed materially during the week, and the interest of the outbreak now centers rather in the few Italian towns in which the disease has made its appearance. In most of those towns it seems to be on the increase, and in some of them the population have become

more or less panic-stricken. A stowaway was reported to have been landed at an Irish port last week, suffering, as the local physicians thought, from Asiatic cholera. A British steamer from St. Lucia arrived at the port of New York last Saturday night, suspected to be infected with the disease, and was detained at the Lower Quarantine for fumigation.

Yellow Fever.—A Norwegian bark, from New Orleans for Gibraltar, arrived off Pensacola on Sunday, and was visited by the quarantine surgeon, who found evidence of the disease on board. By order of the Board of Health, the vessel left for Ship Island.

The Pollution of the Drinking-Water of Philadelphia has lately engaged the attention of the public officers, and proceedings are reported to have been begun against several manufacturing firms, charged with allowing waste products to enter the waters of the Schuylkill from their factories.

The Late Surgeon Woodward.—The Surgeon-General of the army has issued the following:

WAR DEPARTMENT,
SURGEON-GENERAL'S OFFICE,
WASHINGTON, D. C., August 20, 1884.

In announcing to the officers of the Medical Department the death of Joseph Janvier Woodward, Surgeon and Brevet Lieutenant-Colonel, U. S. Army, which occurred near Philadelphia, Pa., August 17, 1884, the Surgeon-General wishes to offer his tribute of respect to the memory of the deceased, whose distinguished career and valuable services, for a period of twenty-three years, have shed luster on the corps, and for whose untimely loss feelings of profound regret will be shared alike by his comrades in arms and by the profession at large.

Dr. Woodward was born in Philadelphia, Pa., October 30, 1833, and was educated at the Central High School of that city, graduating with honor as Bachelor of Arts in 1850, and receiving the degree of Master of Arts from the same institution in 1855.

He graduated in medicine at the University of Pennsylvania, April, 1853; entered the army as assistant surgeon, August 5, 1861; became captain and assistant surgeon, July 28, 1866; major and surgeon, June 26, 1876. "For faithful and meritorious services during the war" he received the brevets of captain, major, and lieutenant-colonel, U. S. Army.

He was assigned to duty in this office May 19, 1862, and from that date until the beginning of the illness which terminated in his death was intimately identified with its professional and scientific work.

While the valuable results of his life's labor are comprehended in a long list of miscellaneous publications, both professional and scientific, too familiar to the corps to require individual mention, his greatest triumphs were won in the field of microscopical investigation in normal and pathological histology, and in his happy application of photo-micrography to the purposes of science. In these pursuits he attained remarkable success, and achieved an enviable, world-wide reputation, leaving to science and medicine lessons of undoubted value and usefulness. Of his strictly professional work, the medical portion of the "Medical and Surgical History of the War of the Rebellion" was the crowning achievement. In the second part of this work he developed the results of his careful investigations into the nature and pathology of the intestinal diseases which had proved so fatal in the late war. Here also he displayed his wonderful capacity for that minute and exhaustive research which forms so striking a feature of his writings.

As in the case of his co-laborer, Otis, he yields to other hands the honor of completing his labors.

In addition to his engrossing professional duties, his restless activity of mind led him to seek recreation in his favorite studies, physics, art, and physiology.

Endowed with a retentive memory and of untiring industry, he acquired a vast store of information which he held available for use at will; fluent of speech, he took delight in the expression of his views and opinions both in social converse and in the arena of scientific debate.

His fund of knowledge, his strong convictions, his tenacity of opinion, and his quick perception made him a controversialist of no low order.

With such a record, it is needless to speak of his zeal, his ambition or his devotion to his profession, and especially to the reputation of the corps of which he was so bright an ornament.

Of a sensitive, highly strung, nervous organization, the confinement, anxiety, and labor to which he was subjected in his attendance upon the late President Garfield during his long illness proved too much for a mind and body already overstrained by incessant labor, and precipitated the illness which finally terminated his life.

At the time of his death Dr. Woodward was a member and ex-president of the American Medical Association, a member and ex-president of the Washington Philosophical Society, a member of the National Academy of Science, of the Association for the Advancement of Science, of the Academy of Natural Sciences of Philadelphia, and of the College of Physicians of Philadelphia. He was an honorary member of several American and foreign scientific, medical, and microscopical societies, and the recipient of many distinguished honors from learned bodies in this country and abroad.

R. MURRAY,

Surgeon-General, U. S. Army.

The Late Sir Erasmus Wilson, according to the "Lancet," so provided by the terms of his will that the Royal College of Surgeons, as residuary legatee, will receive about £180,000, and the Royal Medical Benevolent College, the Medical Benevolent Fund, and the Sea-bathing Infirmary at Margate about £5,000 each.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 17, 1884, to August 23, 1884:*

CRAMPTON, LOUIS W., Captain and Assistant Surgeon. To report at Creedmore, Long Island, N. Y., not later than August 30th, as competitor, and, in addition thereto, as medical officer of the detachment of competitors. S. O. 41, Division of the Atlantic, August 20, 1884.

COCHRAN, J. J., First Lieutenant and Assistant Surgeon. Assigned to duty at the Presidio of San Francisco, Cal. S. O. 81, Division of the Pacific, August 16, 1884.

BIRMINGHAM, H. P., First Lieutenant and Assistant Surgeon. Granted one month's leave of absence. S. O. 162, Department of the Missouri, August 12, 1884.

WILSON, GEORGE F., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Walla Walla, W. T., and to take station at Vancouver Barracks, W. T. S. O. 120, Department of the Columbia, August 13, 1884.

FISHER, W. W. R., First Lieutenant and Assistant Surgeon. When relieved by Assistant Surgeon Cochran, to report in person to commanding general, Department of Arizona, for assignment to duty in that department. S. O. 81, C. S., Division of the Pacific.

WOODWARD, J. J., Major and Surgeon. Died August 17, 1884.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the Navy for the week ending August 23, 1884:*

RIXEY, P. M., Passed Assistant Surgeon. Orders to U. S. S. Lancaster revoked. To continue on special duty.

MARTIN, C., Medical Director. To be retired August 21, 1884.

HEYL, T. C., Surgeon. Detached from U. S. S. Independence and ordered to U. S. S. Adams.

AYERS, J. G., Surgeon. Detached from U. S. S. Adams and placed on waiting orders.

CURTIS, L. W., Assistant Surgeon. Detached from U. S. S. Adams and placed on waiting orders.

STEPHENSON, F. B., Passed Assistant Surgeon. Detached from Navy Yard, New York, and ordered to C. S. S. Bache.

DEBBE, E. Z., Passed Assistant Surgeon. Detached from C. S. S. Bache and placed on waiting orders.

Society Meetings for the Coming Week:

MONDAY, September 1st: British Association for the Advancement of Science (Montreal—fifth day); Brooklyn Anatomical and Surgical Society (private); Morrisania Medical Society (private); Medico-Chirurgical Society of German Physicians; Utica, N. Y., Medical Library Association.

TUESDAY, September 2d: British Association for the Advancement of Science (sixth day); Buffalo, N. Y., Medical and Surgical Association; Ogdensburg, N. Y., Medical Association; Elmira, N. Y., Academy of Medicine; Medical Societies of the Counties of Franklin and Niagara, N. Y., and Hudson, N. Y.

WEDNESDAY, September 3d: Medical Society of the County of Richmond, N. Y.

THURSDAY, September 4th: American Association for the Advancement of Science (Philadelphia—first day); Society of Physicians of the Village of Canandaigua, N. Y.

FRIDAY, September 5th: American Association for the Advancement of Science (second day); Practitioners' Society (private).

SATURDAY, September 6th: American Association for the Advancement of Science (third day); Manhattan Medical and Surgical Society (private).

OBITUARY NOTES.

Dr. C. W. Chamberlain, of Hartford.—Dr. Charles Walter Chamberlain died at his home, in Hartford, Conn., on Thursday of last week, having just passed the age of forty. He was a native of Providence, R. I., and received his academic education at Brown University in that city. He took his medical degree at the College of Physicians and Surgeons, New York, in 1871. He quickly attained to a prominent position in the profession in Connecticut, having settled in Hartford, and for eleven years he was the secretary of the Connecticut Medical Society. At the time of his death he was the president of the Hartford County Medical Society, and one of its delegates to the American Medical Association, and was also the secretary of the State Board of Health of Connecticut, a position which, according to our information, he had held since the organization of the board. He was much interested in public sanitation, and we have often had occasion to quote from his monthly reports. As an individual, too, he had contributed to our columns at various times. Although he was a general practitioner, Dr. Chamberlain gave special attention to laryngology during the latter years of his life. He attended the last annual meeting of the American Laryngological Association, held in New York last May, and seemed then in robust health. We are not informed as to the cause of his death. Dr. Chamberlain was not only of solid repute in his profession; he was also justly esteemed for the manliness of his personal character.

Dr. John H. Dix, of Boston.—Dr. Dix died suddenly, on Monday, the 25th inst., at the age of sixty-five. He was a native of Boston, and obtained his academical education at Harvard, but was graduated in medicine from the Jefferson Medical College, of Philadelphia, in 1836. For many years he was widely known as an ophthalmologist, and he enjoyed a large and lucrative practice in diseases of the eye. He is said to have died of an affection of the heart.

Dr. Clarence E. Black, of the Navy, is supposed to have been lost in the disaster which overtook the United States steamer Tallapoosa in Vineyard Sound on Thursday of last week. He was serving as a medical officer on board that vessel, and, shortly before she went down, he was observed to try to cast himself into the water, but it was thought that he became entangled in an awning and was consequently drawn down and

prevented from gaining the surface of the water. Dr. Black was a native of the Province of New Brunswick. He was appointed an assistant surgeon in the navy in 1871, and in 1875 was promoted to the grade of passed assistant surgeon.

Proceedings of Societies.

CHICAGO MEDICAL SOCIETY.

Meeting of August 18, 1884.

The President, Dr. D. A. K. STEELE, in the chair.

Remarks on Cutaneous Therapeutics was the title of a paper read by Dr. P. C. JENSEN. The integument, he said, retained many of the primitive characters of early embryonic life when it dipped into the interior of the body by deep folds and involutions, to be subsequently differentiated into organs for special function, such as the alimentary canal and the accessory organs, furnishing prolongations for the formation of the spleen, the kidneys, the bladder, the external and internal genital organs, etc. In all instances the excretory organs consisted essentially of liminary membrane, forming part of the integument of the body or its involutions. The lachrymal, salivary, pancreatic, and mammary glands were in like manner composed of a continuation of the liminary membrane of the true skin or of the mucous membrane lining the alimentary canal, involutioned into tubes and follicles the free surface of which was covered with epithelial cells. It was this early embryological relation of the true skin to the internal organs that furnished us with so essential a factor in therapeutics. In cutaneous disease, as in lesions of the internal organs, it was worth remembering that much of the functions of disabled organs could be carried on by the compensatory action of neighboring organs. In congestion of the kidneys we relieved and depleted by bringing the skin and bowels into energetic action, and, by removing the burden, we enabled the overworked kidneys to rest. Conversely, elimination by all the emunctories was essential in the treatment of diseases of the skin. Upon the back of a horse Colin caused water impregnated with potassic cyanide to drip for five hours. The percussion effected destruction of the sebaceous matter, with absorption of the cyanide, and poisoned the animal. In Vienna patients had remained immersed in a bath for weeks and months without any perceptible degree of absorption taking place. Usually the small quantity of material absorbed was introduced either by points of transition between the skin and mucous membrane, or by the orifices of the sebaceous and sudoriparous glands. When the cutaneous surface of a limb was immersed in putrid gases absorption took place (Bichat), and the poison was subsequently eliminated by the bowels. The rate and degree of absorption of any medicine would depend largely upon its power of diffusion. Physiologically, the skin might be considered a colloidal septum, on one side of which lay the blood-vessels containing an alkaline fluid, while there was an acid on the other side—a condition most favorable to osmosis. Medicinal substances in aqueous solution slowly permeated the skin to enter into the circulation. Alkaloids dissolved in chloroform were readily transferred through the skin into the blood-vessels, while alcoholic and aqueous solutions were either not absorbed at all or only very slowly, according to Waller, whose observations had been made with chloroformic solutions of atropine, aconitine, morphine, and strychnine. The same physiologist had ascertained that alcohol mixed with chloroform did not retard absorption, but that alcohol alone caused an osmotic flow.

With these remarks as a foundation, the reared proceeded, to consider the *local treatment of skin diseases*, including, 1. Protection, the exclusion of air when its contact was injurious; 2. Cleanliness, through ablutions, the removal and prevention of diseased products; 3. The checking or limiting of liquid disease-products, whether sanguineous, sebaceous, serous, or puriform; measures to enable the remedies to act directly, without injury to the surrounding parts. To fulfill these requirements we had: (a) plasters, (b) ointments, (c) tinctures, (d) dry powders, (e) alcoholic and ethereal solutions, (f) chloroformic solutions, (g) oleo-palmitates. Those most commonly used were the metallic oxides and the salts of the following metals: lead, silver, mercury, zinc, copper, and aluminium. There were also various astringents, sedatives, and anodynes of organic origin. Of the local remedies, the more recent ones were salicylic acid, chrysarobin, chrysophanic acid, pyrogallic acid, and naphthol. Tilly Fox had used goa-powder formed into a paste with water, applied to psoriatic patches, and retained in position with collodion. Sesemann employed chrysophanic acid six grammes, to collodion four grammes. Pick recommended chrysarobin gelatin of different strengths, and applied glycerin over the gelatin. Unna had proposed chrysarobin plasters; Müller, ointments of chrysophanic acid spread on muslin; but all these methods would often produce dryness, irritation, pain, and tenderness, and therefore they were impracticable. Dr. Kohn used a solution which he termed traumaticin, consisting of one part of gutta-percha in two parts of chloroform. It was said to form a thinner and more delicate covering than collodion or gelatin, causing neither tension nor pain. Traumaticin was a neutral covering and protective remedy. Ten-per-cent. solutions of it, when applied to large surfaces, did not cause irritation; besides, it produced more uniform pressure than collodion, glycerin, or gelatin.

The writer has treated a number of cases of psoriasis and obstinate chronic eczema substantially as follows: In most cases there was either a debilitated constitution, a gouty diathesis, anæmia, neurasthenia, or the like. Particular attention was paid to each constitutional dyscrasia. Eliminants were used to remove waste products and toxic *débris*, and for their derivative effect. Locally, after the removal of crusts, etc., an alkaline lotion was thoroughly applied, causing saponification of the sebaceous material and inducing an alkaline reaction favorable to osmosis and absorption. Thus:

Bicarbonate of sodium,	3 j;
Caustic potash,	3 ss;
Water,	O. j.

The following ointments had answered admirably in the writer's experience:

Powdered camphor,	3 ss.—3 j;
Chloroform, enough to dissolve it;	
Chrysophanic acid,	gr. xx;
Powdered opium,	3 ss.;
Cosmoline,	3 j.

This was to be applied after using the alkaline lotion. Tannin might be substituted for the chrysophanic acid, and vaseline for the cosmoline. Chloroform solutions were clean and effective. The following should be applied with a soft sponge:

Camphor,	3 ij;
Chrysophanic acid,	3 ss.;
Tincture of opium,	f 3 ss.;
Squibb's chloroform,	f 3 ss.—j;
Alcohol, enough to make	f 3 ij.

Carbolic acid might be substituted for the chrysophanic acid. The writer had also tried liquor gutta-perchæ as a vehicle

for chrysarobin and tannic and carbolic acids, and had found it very efficient.

The paper concluded with a general description of some of the neuralgias accompanying cutaneous disease, and gave a number of new formulae, among them the following, for local application in neuralgia of the fifth nerve, which would give marked and often instant relief:

Menthol,	3 j;
Sulphate of morphine,	gr. iij;
Tincture of aconite root,	f 3 ij-ii j;
Chloroform,	f 3 ij;
Spirit of camphor,	f 3 ij;
Dilute phosphoric acid,	gtt. xx.

The acid was added to favor absorption.

The cause of the neuralgia, which was symptomatic of some pathological condition, should be sought for and, if possible, removed, in order to effect a permanent cure, but the application alluded to would almost invariably afford relief.

Dr. C. E. WEBSTER inquired if using the oleates to act on the fatty substance would not be equivalent to using an acid to favor absorption; and, if it would, whether we could not get a double advantage by using both an oleate and an acid simultaneously.

Dr. H. J. REYNOLDS thought well of the paper. Regarding the causes of some of the skin diseases, he thought over-taxing of some of the organs and insufficient action of the skin at times would produce them. In the former case, where an organ has been overworked, defective action of some of the other organs might co-exist. Weather and climate had much to do as a cause. Some skin diseases prevailed in cold weather, as, for instance, psoriasis; while others were prevalent during the hot season. In the treatment, the great aim should be to perfect the equilibrium of the action of the skin and other organs. We relied too much on so-called specifics, and, in doing so, we were often defeated in bringing about the desired result unless the other idea was borne in mind—namely, to secure free action of the skin and other secretory organs. Although the few specifics, such as mercury, iodine, quinine, and arsenic, would enter largely into the treatment of these affections, there were external causes much more frequently present than we were generally led to suppose. The digestive tract also needed to be looked to. Another agent that might cause some of the forms of skin disease (singularly enough) was electricity. Just how it did it was a question which he was not fully prepared to answer; but, again, electricity was frequently of great service in the treatment of skin disease. He was sure its value was frequently underestimated, as nothing fulfilled certain indications for treatment so well as the application of electricity.

Dr. C. W. EARLE inquired if using chrysophanic acid, gr. xx to 3 j, would not cause an erythematous condition of the surrounding parts. Should we expect this from using the remedy in any strength, or was this proportion too strong?

Dr. JENSEN had used the oleates of zinc, mercury, and copper a good deal, and he had found them to be efficient remedies, easily absorbed and easy to apply, and they were very neat, but he had not used them so extensively as he had the acid preparations. Irritation from chrysophanic acid occurred when it was used in considerable strength, but adding opium or bismuth to the preparation would prevent this to a great extent, or the strength might be reduced.

Dr. REYNOLDS stated that chrysophanic acid was more apt to cause an eruption of an erythematous character when it was used while arsenic was given internally. The irritation was of a mild inflammatory order, analogous to what occurred to the mucous membrane of the stomach when arsenic was given for too long a time, or in too large doses.

Infant Feeding and the Summer Diseases of Children.

—Dr. EARLE read an elaborate paper on this subject, dealing largely with the prepared foods to be found in the market. He summed up his conclusions as follows:

"1. The most frequent infantile disease in the city during the summer months is entero-colitis.

"2. Excluding causes of infant mortality largely beyond our control, improper feeding is one of the chief causes of the great number of deaths among this class.

"3. Mothers should nurse their children. In lieu of this, a wet-nurse should be procured. If this is impossible, a mixed diet should be resorted to.

"4. Artificial foods containing considerable casein are found to be a cause of indigestion and summer disease.

"5. In many cases, cow's milk, diluted with water, does not seem to agree with children. Barley-water or rice-water as the diluent seems to make a more physiological food.

"6. Condensed milk seems to agree with a considerable number of children, but in many cases sufficient is not used to nourish a child. Used in proper quantities, and diluted with rice- or barley-water, it is without doubt one of the best of artificial foods.

"7. Cream, mutton broth, and white of eggs are valuable adjuncts in the diet of children.

"8. Whatever the artificial food a child is having, the physician should examine it frequently for evidences that it is a proper food as regards quality and quantity. The normal elevation of the fontanelles and increasing weight are among the conditions denoting a satisfactory and favorable nutrition."

Dr. J. S. KNOX judged from the paper that its author had been a bottle-fed baby, as he himself had been, and inquired if this was true. [He was answered affirmatively.] He differed a little with the writer regarding the causes of entero-colitis and other allied bowel affections of children, relative to improper diet. This in part was a cause, but the principal causes arose from or were peculiar to the hot weather of summer. Heat produced nervous exhaustion in a child. It became restless, and the fontanelles depressed. Therefore, the trouble at first was that the nervous system was depressed or exhausted. Urgent thirst came on. Then, too, children were wrapped up too much; the bottle-fed child especially was wrapped in flannels by the mother, and then it became more thirsty. It was probably fed on milk that had "soured," or on farinaceous food that had become fermented, either of which, probably, was given frequently. The heat and this form of diet produced fermentation in a child's stomach—indigestion, diarrhoea. A child from three months to ten years of age might need diffusible stimulants in the morning of a hot or sultry day. A little spirit of camphor, aromatic spirit of ammonia, or valerianate of ammonium, or even whisky-toddy, he had often given to his children, and none of them have ever yet had so-called summer complaint. For thirst, children should be permitted to drink good pure water, and they should be fed at regular intervals (not too frequently) with farinaceous articles that should be freshly prepared only at the time of administering them, and given no oatmeal. If Ridge's food was given, it should be prepared with cream, withholding milk at the time. Gruels and lime-water should be given. The secretions should be tested with litmus-paper to ascertain their reaction. Excessive heat would be most likely to produce a "heat diarrhoea." When the temperature was hot, he would give a child, when necessary, three, four, or even six cold baths a day. He had seen children go to sleep while in a cool bath. This should be done on the same principle as in typhoid fever. The cause was more apt to arise from heat, such as we had here during August, and exhaustion,

fermentation, irritation of the stomach and bowels, and interference with nutrition; and finally catarrhal diarrhoea supervened.

Dr. F. E. WAXHAM differed with the writer and the previous speaker as to the causes. The greatest cause was the combined effect of improper feeding, heat, and impure air. If the trouble was due to improper feeding, babies would die as readily in the country as in New Orleans, San Francisco, or New York. If it was due to excessive heat, they would die as readily in our better city districts, or in the country, where there was impure air, as in the poorer localities, where the houses were ill-ventilated and stifling with heat, where perhaps several children lay in one bed, where the air was tainted with filth—this, with sudden fluctuations of temperature, would produce a greater number of cases. Greater fluctuations of temperature occurred in Chicago, New York, Boston, and Omaha, than in New Orleans and San Francisco. It was more uniform in the two latter cities, and, when no other causes were present, children did not die in these cities so readily as in the others mentioned. With reference to cerebral symptoms, what was the reason, significance, and treatment of them? If a convulsion came on during an attack of enterocolitis, was it a result of reflex or of cerebral disturbance? It was the result of pain, and we should resort to opium and the bromides. There might be impending danger of hydrocephalus or meningitis. There might be blood stasis under the finger-nails. Now, was it not reasonable to suppose that a serous exudation might occur in the ventricles—analagous to that which we sometimes met with under the finger-nails—from want of tonicities in the blood-vessels? If so, we must give the child quinine and stimulants. It might be a gradual softening of the brain coming on. The speaker then cited a typical case of cholera infantum—in which the patient had been for two weeks at the point of death—that had, as he supposed, passed through these various stages of disturbance to the brain corresponding to the blood-stasis under the finger-nails. The child ultimately recovered.

Dr. D. M. TUCKER thought children did not require whisky-toddy in the morning before they had been taken sick, as one gentleman had stated. The same was true also in obstetrical cases, where a nurse generally wanted to give toddy to a baby almost the very first thing she did. Usually we were not called to see a child until it had become pretty sick—very sick. The very first thing we should do, then, was to regulate the diet early, if this needed to be done. If the baby had had toddy administered to it, we should order this sort of medication discontinued.

Dr. E. F. GASTON was of the opinion that the death of babies should frequently be attributed to inanition. The use of mixed diet, diluted milk, and condensed milk was in many instances over-done—the little ones did not get sufficient to sustain them. This applied particularly to infants that were bottle-fed, a few months old.

Dr. JOHN BARTLETT thought the sweetness of condensed milk was destructive to digestion, and that that feature was against its use. The causes of summer diarrhoea, of course, were several. Whether heat, sudden atmospheric changes, irregularity of diet, the constitution of a child, fermented foods, etc.—all these, no one would deny, were causes. He had had good success from using peptonized food, the pancreatic extract prepared by Fairchild, and other varieties, but did not wish specially to recommend either of these as being absolutely superior to some of the other varieties.

Dr. J. E. WALTON inquired of the last speaker how frequently he would order the prepared foods he had named to be given.

Dr. BARTLETT replied every three or four hours.

Dr. J. J. M. ANGEAR said that, according to physiologists,

children could not digest starch until there was saliva; and yet starch was given them in the treatment. From his observation, the most frequent cause of these summer troubles was over-feeding. Then, too, some cows' milk disagreed with children, and we wondered why. The milk of cows improperly cared for would present nearly all the prismatic colors of the rainbow if allowed to stand for a short time. This milk, he had been informed, was given to children in the Fourteenth Ward, about Chicago Avenue, where the greatest mortality among children occurred. If this was true, it should be remedied. He had been told that in London cans of milk designed for children were sealed by an official. If this idea was carried out here, our little ones would get better milk. How did heat produce the disease, or act as a cause? By depressing the nerve-centers. The heat affected not only the cerebral centers, but the cells of every part of the body. Heat at first stimulated these cells, then the cells died and contaminated the blood, and this material entered the bowels. The cold-water bath was one method of saving the vitality of these cells.

Dr. H. J. REYNOLDS thought, regarding the ætiology of enterocolitis, that, besides heat, imperfect feeding, filth, impure atmosphere, placing a child in a heated room, etc., a peculiar atmospheric condition, coincident with or without any of the other causes, might produce the disease. Electricity, conjointly with this peculiar condition of the air, might have much to do with the result.

Dr. C. E. WEBSTER said, respecting starch as a food for infants, that it might be interesting to note that recent experiments had demonstrated that the saliva of infants was capable of converting starch into sugar as early as the sixth day after birth. Deductions as to the practical value of this discovery were limited, however, by the fact that the saliva was a very small factor in the digestion of starch; the intestinal and pancreatic juices must aid. The matter of the digestion of starch by infants required further investigation.

Dr. G. C. PAOLI thought opium was a very frequent cause of the death of little children with cholera infantum. They should have better diet and plenty of fresh air, and, lastly, more hospitals for children should be built. We were deficient in this respect. Hospitals would do much toward saving children from the slums and alleys, where the poor have stale bread, and where decaying vegetable matter was constantly found polluting their scanty homes.

Dr. F. H. MARTIN spoke of the sanitarium recently erected at the foot of Twenty-fifth Street, on the Lake shore, carried on by Jewish ladies. A few healthy cows were kept there that were grass-fed, and given clean bran and good water; and from twenty-five to fifty babies were fed daily on fresh milk and biscuit.

A Theory of the Cholera.—Dr. JOHN BARTLETT read a paper with this title. While it must be admitted, he said, that our knowledge of the disease was very imperfect, it might be of interest and profit to frame some theory of it which should conform to every known fact regarding it, and which might afford explanations of the phenomena as satisfactory as our limited knowledge of such subjects would in the present state of science admit of. Such a theory would be of value, if simply as a framework which might hold together, in an apparently perfect order and relation, a large number of fragmentary facts that might be lost sight of if allowed to lie detached and disconnected.

Events were occurring about us similar in many particulars to the rise and spread of epidemic diseases. One of the most striking of these, perhaps, was the prevalence of that plague to vegetation, the army worm. The laws of this pest had something in common with those of cholera. Thus, the cause of the army worm was always present in, and indigenous to, certain

localities favorable to its development, life, and methods of propagation. Appearing yearly in these habitats, it spread occasionally, and with some show of periodicity, over extents of territory far beyond its normal range; and these periodic irruptions frequently covered vast areas of territory, carrying devastation over continents. In this march outward from the nidus of development, pushing onward by somewhat regular yet occasionally interrupted stages, the army worm resembled an epidemic of disease in its mode of approach to a place, its gradual attainment to an acme of destructiveness, and its final abatement. Thus, the army-worm millers indigenous to certain marshy lands of the South, in the year 1861, sallied from their haunts in illimitable swarms and deposited their eggs in suitable places and at a suitable period of the growth of early vegetation in every county from the Gulf to the lakes. These eggs lay dormant until stimulated by the warm weather. Then, apparently, starting from its habitat at the southward, began the northward march of the army worm which overran the country. It was because of the fact of the apparent onward march of the countless hosts of these invaders that they had received the suggestive name of the "army worm," and yet their march was only apparent. They moved only from field to field, like other insects, for the purpose of forage. They advanced northward only as the peach blossom advanced northward; their march kept pace with the increment of heat of the advancing season necessary for the development of the long-deposited eggs. The line of their advance was an isothermal one. Thus the worms, keeping pace with vegetation, appearing when the winter wheat was "in the milk," advanced toward the North slowly, so that they appeared in Maine two months after they were first seen in Missouri. After several weeks the destroying agents disappeared. They had not moved on to other conquests, as people supposed, but the worm, disappearing under the sod, had become a chrysalis, which in a few weeks emitted the miller, that deposited its eggs—and thus was completed the cycle of the insect's life. It had been assumed by some that the whole field devastated had been sown with the germ of the plague the previous season. Observation of the insect indicated, however, that it passed through its phases within a few weeks; and it was probable that the visitation was not thus sown broadcast and at one time, but that the invasion was the gradual encroachments of successive "crops" of the worm. The insects marching northward into Michigan were not contemporaries, but the descendants, by several removes, of those which weeks before had invaded southern Illinois. Thus a brood of worms, disappearing in the northern counties of Mississippi as chrysalides, was represented in a few weeks in middle Tennessee by millers attracted northward in search of early vegetation suitable as nidi for their eggs. The crop of moths from these eggs would in turn deposit their ova in Kentucky, and so the advance northward would be effected—not by the worms, but by that element of the insect floating in the air and endowed with the power of swift flight and with a selective instinct. In regard to the continuance of the recurrence of these insects, it was essential that the several elements should find suitable resting surfaces and conditions of temperature, moisture, etc. In the lack of these, the element might perish, or might remain inactive for an indefinite period, till conditions occurred capable of arousing it to development. Thus, in the latitude of St. Louis, with favorable conditions, two or three broods of the worm were hatched in one season; while in Maine a second brood did not appear. Injury to crops wrought by secondary broods in one locality was comparatively limited. The new worms were preyed upon largely by enemies now come into the field, and material suitable for their sustenance was scarce, in good measure exhausted by the

depredations of their predecessors. Finally the miller of the army worm "wintered over" and deposited its egg at the appearance of vegetation in the spring.

By accident or design, the insect, in any of its phases, could be transported to any distance, and as a miller it might be readily carried by the wind. Dr. Koch, the noted microscopical investigator of the causes of disease, believed that he had discovered the actual entity producing the cholera in a fungoid cell, the "comma bacillus." As yet no more was known of this bacillus than its bare existence. It had a natural history, but the laws of its development and changing growth were yet to be learned. In the absence of such knowledge, we might assume that it had certain phases of development, as the army worm had, and that in each one of these it presented different potentialities. In relation to certain fungoid cells, the fact of such phases of existence was ascertained, and from analogy it might be inferred that the comma bacillus, after a period of active growth, developed into apparently lifeless-formed material, a crystalline substance, bearing, so to speak, the same relation to the cell as coral bore to the insect which formed it. This crystalline substance was not dead but living matter, and, after a period of passivity, under favoring circumstances it put forth buds, which presently burst and emitted into surrounding media a protoplasmic fluid in which in time were developed the cells, thus completing the cycle of changes in the life of the plant.

The peculiarities of the several elements might be thus stated: The crystalline substance, as had been remarked, was in the form of dust, granules, or threads—not an impalpable something, but a material which might be seen with the naked eye and handled with the fingers. Under the microscope it might be seen to form from an aggregation and concretion of cells. From it buds, sprouting, emitted what might be compared to the contents of an egg, a protoplasm, an apparently homogeneous aqueous fluid, in which presently there began to appear dim outlines of cells that gradually grew in size and increased indefinitely, not from cell division, but from the development of a cell from every atom of the protoplasm. The power of this fluid was only exhausted when its ultimate atom had become a cell. The characters of the protoplasm prior to the development of cells would probably elude all efforts at recognition, so that the fluids and tissues of a body containing it might be examined with the highest power of the microscope without the detection of any organic particles.

All parts of the cholera fungus, then, were portable; all were tangible, visible entities, except the infinitely minute atoms of cells in the protoplasm. The entrance of this fluid into the economy impregnated the system with the ultimate germ of the cells, which, under favoring circumstances, developed at the expense of the blood and produced the symptoms known as cholera. The seeds of the disease were brought in the course of travel to a locality as crystalline substance, cholera dust, or protoplasm diffused in the moisture of the air, or water, or in the fluids of the human body, in the form of cells. Under favoring conditions these elements proceeded to perform each its part in nature, so that, sooner or later, after finding a resting-place in a community, they developed protoplasmic fluid which, disseminated by the law of diffusion of fluids in the air and water, or resting as the dew upon articles of food, found its way into the body. The atoms of this poison, infinite in number and pervading large areas of space, were received into the system of all, like the pernicious miasm of the marshes. The blood, acting as other fluids had been observed to act when impregnated with fungi, resisted the changes which it was the destiny of the foreign agents to effect until the number of the invaders, or some changes in the vitality or chemistry of the impregnated

fluid, made longer resistance impossible, and an explosion of the disease, like a paroxysm of pernicious fever, resulted. The ejecta from the first cases, filled as they were with cholera-cells, found their way generally to a favoring soil, and developed within a few hours succeeding phases of the fungus. Thus crop after crop of cholera atoms were begotten in a prodigiously increasing progression, to extend the area of infection and increase the malignancy of the disease. It might happen that the germs of cholera introduced into a locality found circumstances unfavorable for their development at the time; and, although the seeds of the disease might be pretty generally sown, they would lie dormant for a season.

There were certain known facts regarding the cholera which at least lent plausibility to the theory that the germ might be implanted in a district long in advance of the actual appearance of the disease. Such, certainly, was the case when the cholera "wintered over," as it was said, lay inactive, it might be, through the autumn, winter, and spring, to rise into activity the following summer. It had long been noticed that an epidemic of cholera was often preceded for weeks by the influenza, and a marked and general tendency to diarrhoea. The reasonable assumption that both the forerunning ailments and the succeeding disease were the effects of a common cause would imply the presence of the germ of cholera in a locality long before the actual outbreak of the epidemic. The march of the pestilence, though generally in the track of travel, was sometimes singularly abnormal as to this law. The cholera sometimes sprang up in places far out of the line of apparent exposure. These variations and exceptions to the general law of portability of the disease suggested a possibility of the truth of the theory that it might be primarily sown as a temporarily inactive dust, as well as implanted as a speedily developing protoplasm. It might be that, in attempting to trace the origin of the disease by noting in any locality the first case, we erred in this, that we compared the course of the epidemic with the line of travel in the presence of the attack, when possibly it was the course of the traveler from the infected district of last year to which attention should be given. The irregularity as to the time and place of appearance might be further referred to the varying soil and temperature of the respective localities considered as developing agents of the deposited germs.

It would be noted that there had been here set forth two theories as to the mode of advance of cholera: the one, that it advanced in successive crops from a first or isolated case; the other, that the seeds were sown broadcast over the countries elected for visitation, and that these were developed as favorable conditions arose. The number of cycles which the cholera germ might undergo in a season varied probably with the locality, temperature, etc.—conditions which determined the severity of the epidemic and the length of its stay in a place. Thus, at St. Louis, the number of its cycles might be threefold greater than at Bangor; and a variation in the time of the cycle, also, might influence the rate of advance of the disease.

Changes in the blood effected by the protoplasmic atoms in their act of development into cells alone produced the cholera; the presence of cells which had already completed their growth, or the material formed from them, cholera dust, did not directly induce the disease. Thus rice-water discharges abounding with the comma bacillus might be drunk without injury. The subsequent deposit of these cells in the ejecta of the experimenter might, however, lead to an outbreak of the disease of which he might prove the first victim.

One of the most singular laws of the cholera was this, that, with rare exceptions, it marched *onward*. It remained active in a place a number of weeks and subsided, and the places next attacked were *beyond*, relatively to the starting-point, the dis-

trict last devastated. In the case of the army worm also this was the fact; and, in regard to the march of the insect, we can plainly discern the laws, whether it was held that the eggs had been all deposited by the same army of moths, or by successive broods of them. In the one case, as the writer supposed, the millers, finding the fields of favorable deposit "pre-empted," passed onward to unoccupied territory. In the other, because of the devastation made by the preceding generation, the millers of the present must instinctively move onward in search of proper resting-places for their eggs.

Now, as the army worm moved onward by instinctive selection, might it not be possible that the cholera fungus advanced by a *vis a fronte*—a species of chemico-vital affinity—a diffusion in the direction of affinities not yet exhausted, just as the small-pox virus dwelt in a community till its affinities for all were expended, and then moved onward in the direction of the unprotected?

To the student of cholera the parallel furnished by the army worm as to the convection of its elements, and the possibilities and proper times and methods of quarantining against them, was suggestive.

Means by which man might "stamp out," or keep out, the myriads of army worms which sometimes in a few hours filled to the brim the cordons of ditches plowed about the grain-fields, and changed in an equally short time flourishing acres of wheat into a "marble ground," could hardly be devised. Plans by which he might unearth and devitalize chrysalides, planted under every sod from Georgia to Maine, were difficult to imagine. Methods by which he might successfully contend against the innumerable moths filling the air, might discover and destroy the numberless eggs deposited in every meadow on the continent, were inconceivable.

How infinitely more difficult to avoid, or to antagonize, were the minute cells, the every-way and everywhere portable dust, and the invisible, intangible, miasmatic atoms of the cholera!

And yet the farmers actually did antagonize their protean plague in all its phases, and with a fair measure of success. They quarantined against the ever-coming and ever-increasing countless millions of worms. They energetically and persistently worked to keep off from yet uninvaded fields, by means of a cordon, mechanical and chemical, all possible insects; they plowed under and deeply buried, in order to destroy, the chrysalides known to have formed; they attempted to entrap and destroy the millers by cordons of lights, and they burned the grass where the eggs were deposited.

The principles of quarantine against the cholera suggested by the theory of the disease here presented might be summed up in the following propositions:

Elements of the disease known to exist might be isolated or destroyed.

Places suitable for the development of the elements might be rendered unsuitable.

Ingesta, possibly contaminated by the cholera poison, might be avoided.

Badly infected districts might be evacuated.

According to this theory, during an epidemic the poison lurked in the individual. In the blood of an exposed person there were two contending forces—the one the resistance of the vital fluids to the changes attempted to be made by the invading atoms, the other the efforts of the latter to appropriate from the blood materials for their own growth.

One of the first evidences of the yielding of the forces contending for the integrity of the blood was loss of serum. The one important event in the chemical change in the blood necessary to give the victory to the ferment (invading atoms) was loss of its serum. Speaking figuratively, serum was the essen-

tial ally of the blood in its resistance to the invaders. The ejection of ever so little of this tended to render the ejection of other portions easier, and to give the final victory to the poison.

Now, while no prophylactic measures were known, it was most fortunate for mankind that remedies were at hand which, if applied in season, might, unless the assault of the ferment was overwhelming, arrest the flow of serum and re-enforce the blood in its resistance to the infection.

Even when the cholera had held full sway, when it had run its course without interference, it was not necessarily fatal, either because the dose of the poison had been insufficient to destroy, or because in some life might continue after the virus had done its worst.

The secondary reactionary conditions following the collapse, known as the typhoid state, were complicated phenomena. They were expressions of the efforts of the system in its struggles with the resultants of the cholera paroxysm, rather than a proper stage of the disease. They bore a relation to cholera which might be compared to that which surgical fever bore to the injuries which caused it.

This theory of the presence of the germ of disease in the system of all involved the recognition of the principle of acclimatization in this disorder. One might become by gradual inurement habituated to the presence of the virus, and perhaps the majority so inured were able completely to resist it. As in yellow fever, however, the acclimatization might be speedily lost. Persons whose systems had not thus become acclimated to the poison might be, upon sudden exposure, stricken down with violence.

[The paper provoked much discussion and inquiry, which, on account of limited space, we are obliged to omit.]

LISTON H. MONTGOMERY, M. D., *Secretary.*

Reports on the Progress of Medicine.

ANATOMY AND PHYSIOLOGY.

By GREME M. HAMMOND, M. D.

The Effects of Premature Synostosis of the Cranium.—Dr. E. Zuckerkandl's fourth contribution ("Med. Jahrbücher," 1883) on the subject of the anatomy of the human body is occupied with a discussion of the influence of ostosis of the cranial sutures and the formation of the skull upon the direction of the convolutions of the brain. Meyer, Meynert, and Rüdinger have demonstrated that there is a certain and constant relation between the shape of the skull and the direction of the convolutions of the brain; that the convolutions of a brain contained in a dolichocephalic skull run more in a sagittal direction, and that when the skull is brachycephalic the direction of the convolutions is more frontal. Zuckerkandl concluded that, if these views were correct, the normal direction of the convolutions might be altered through other influences, such as, for instance, the premature ostosis of the cranial sutures. He therefore collected six cases, from which the following observations were obtained:

CASE I.—The skull was abnormally long, and premature ostosis of the sagittal suture existed. The brain was elongated and narrow. The orbital lobes were peculiarly formed in both hemispheres. They were bent downward and pressed against a corresponding part of the temporal lobe. The frontal lobes were elongated, and their convolutions extended in a sagittal direction.

CASE II.—The brain was taken from a scaphocephalic skull.

The frontal lobes were wide at the base but narrow toward their anterior extremity, and their convolutions, packed closely together, ran in a sagittal direction.

CASE III.—The brain was taken from a dolicho-acrocephalic skull in which premature ostosis of the sagittal and coronal sutures had occurred. The shape of the brain was acrocephalic. The frontal lobes were small, especially in the orbital region, and were bent upward. The gyrus rectus was drawn out in both hemispheres in the shape of a beak. On the convex surface of the brain the convolutions of the frontal lobes were very narrow. The temporal lobes were short and thick, and their convolutions broad and massive. The anterior portion of the gyrus occipito-temporalis lateralis protruded above the surface of the brain.

CASE IV.—The brain was taken from an acrocephalic skull in which premature ostosis of the frontal suture had occurred. The orbital lobes were similar to those mentioned in the preceding case. The frontal lobes were small, and the temporal lobes broad and full. The occipital lobes were bent downward and sloped to a point.

CASE V.—The brain was taken from a dolicho-acrocephalic skull in which premature ostosis of the sagittal and coronal sutures had occurred. The brain was elongated, and tapered to a point posteriorly. The orbital lobes were somewhat misshapen. The frontal lobes were small, with numerous convolutions, and the occipital lobes bent downward.

CASE VI.—The brain was removed from a dolicho-acrocephalic skull in which premature ostosis of the sagittal and coronal sutures had occurred. The brain was a little longer and more pointed, posteriorly, than the one mentioned in the preceding case, but the malformation of the orbital lobe was not so apparent. The frontal convolutions were small and tortuous. On the left side the middle convolution of the temporal lobe projected above the level of those adjacent to it. The gyrus fornicatus, gyrus fusiformis, and gyrus temporalis superior were strongly marked and projected above the rest of the misshapen lobe. The cuneus was small on both sides.

Zuckerkandl concludes, from these cases, that the brain does not always correspond in shape to the form of the deformed skull. That in elongated skulls the frontal lobes are small, their convolutions narrow and pressed together; the temporal lobes are massive, and project above the surface of the rest of the brain. In premature ostosis of the sutures in a dolichocephalic skull, the convolutions, especially in the frontal lobes, run in a sagittal direction.

On the Coagulation of the Blood.—Dr. L. C. Wooldridge ("Journal of Physiology," Feb., 1884) continues the subject of the influence of lecithin in producing coagulation of the blood. In former experiments peptone plasma was used. In the present case he made use of blood which had been prevented from coagulating by being, immediately after leaving the body, cooled down to a temperature of 0°. Coagulation of the blood is brought about by a certain interaction of the white corpuscles and the plasma. By rapid cooling, this interaction is suppressed, and hence the blood does not coagulate. But, if one of the substances of which the white cells are made up be diffused through the cooled blood, coagulation does occur. This substance is lecithin. The method of experimenting is as follows: The blood is taken from a large artery and flows into two thin metal tubes of about half an inch diameter. The tubes stand in large vessels filled with broken ice and a little water. Each tube holds 40 c. c. One contains 15 c. c. of .6 per cent. NaCl solution, the other a similar quantity of normal salt solution through which finely emulsified lecithin is diffused. Numerous experiments performed in this manner showed that the blood in the tube containing the lecithin was coagulated in ten or twenty

minutes, while the blood in the tube containing only the salt solution showed no signs of coagulation even after standing one hour. The lecithin used was prepared from lymph-glands. It had a slightly acid reaction, and was not perfectly pure. It was rubbed up with a drop or two of dilute Na_2CO_3 solution to a paste, and then diffused through the salt solution.

The Motor and Inhibitory Nerves of the Rectum.—Dr. Leopold Fullner ("Med. Jahrbücher," 1893) has lately made some very interesting experiments which show conclusively that the rectum is supplied with both motor and inhibitory nerves. His method of procedure was to fix a hook securely to the lower portion of the rectum, and then, by means of a double ligature, cut through the rectal tissue one centimetre below the point of fixation. To this hook a cord was fastened, which, passing over a pulley, communicated with the lever of Bach's recording cylinder, the tracing lever of which registered each contraction of the rectum on the revolving drum of Balzer's kymograph. Dr. Fullner, after having performed a great number of experiments, arrives at the following conclusions:

1. The motor nerves of both systems of muscular fibers, the longitudinal and the circular, run in separate channels. The motor nerves for the longitudinal fibers are known as the "nervus erigens." They arise in the sacral plexus and are lost in the hypogastric plexus. The motor nerves for the circular system lie in one of the descending pairs of nerves of the posterior mesenteric ganglion. They are known as the hypogastric nerves, and are likewise traced to the hypogastric plexus.

2. The rectum possesses two different kinds of inhibitory nerves, one controlling the longitudinal fibers, the other the circular fibers.

3. These inhibitory nerves also run in different channels, but finally each inhibitory nerve forms a common trunk with a motor nerve supplying the antagonistic muscular system, so that the nerves descending from the sacral plexus are not only motor nerves for the longitudinal muscular system, but are at the same time inhibitory nerves for the circular fibers, and the nerves springing from the posterior mesenteric ganglion carry inhibitory impulses to the longitudinal fibers, and at the same time are motor nerves for the circular system.

4. By this arrangement it is possible that, at the same moment when motor impulses are generated in one set of muscular fibers, an inhibitory action may occur in the antagonistic system.

5. In accordance with this, the observations show that during the spontaneous dyspnoic and post-mortem movements of the rectum both systems of fibers do not usually act together, and that the contraction of one set of muscles does not begin before the antagonistic action in the other system ceases.

6. The action of the inhibitory nerves is to lower or abolish the tonus—that is, the contractility of the muscle in question.

7. The effect of electrical irritation of one of the motor nerves shows itself by the suppression of the irritability of the proper inhibitory nerve. It also produces an antagonistic relation between the two nerves of one muscular system.

The Action of Rubidium and Cesium Salts compared with the Action of Potassium Salts on the Ventricle of the Frog's Heart.—The close chemical relationship between potassium, rubidium, and cesium has led Dr. Sydney Ringer ("Journal of Physiology," Feb., 1884) to investigate the degree of physiological correspondence between rubidium and cesium on the one hand and potassium on the other. The experiments were made with the ventricle of the frog's heart attached to a perfusion cannula by a ligature placed as nearly as possible in the auriculo-ventricular groove. Artificial circulation was maintained through the ventricle by a siphon action. The contractions of the ventricle were recorded upon Roy's tonometer.

"It is necessary," says Dr. Ringer, "to preface the experiments with rubidium and cesium with a brief statement of the physiological action of potassium on the frog's heart."

When the circulating fluid supplied to the detached ventricle consists of a simple saline solution, the contractility first grows weak and then gradually recovers itself. A physiological dose of potassium chloride prevents this recovery.

When the ventricle is fed with a saline solution containing a physiological quantity of a lime salt, diastolic dilatation is much retarded. A potassium salt accelerates this dilatation.

Sodium carbonate and sodium bicarbonate added to the saline solution broaden and cause much fusion of the beats, and induce tonic contraction. Potassium chloride obviates all these effects.

With a blood mixture (dried bullock's blood dissolved so as to imitate fresh blood, and diluted with two parts of a saline solution made with tap-water), potassium salts greatly prolong the latent period and the period of diminished excitability, and lessen the frequency with which contractions can be excited by electricity.

With the blood mixture, faradization induces tetanus, but, when a potassium salt is added, faradization arrests the contractions, which recommence on discontinuing the faradization.

Potassium salts arrest the ventricle in diastole.

A number of experiments which were performed demonstrate that in all the foregoing particulars the action of rubidium corresponds exactly to the action of potassium. The case is far different with cesium, the physiological action of this metal being more like that of barium and strontium. Two hundred c. c. of saline solution containing 2 c. c. of 1.685-per-cent. solution of cesium chloride soon broadened the beat and caused tonic contractions. Ten minutes later the beat became greatly broadened, and the ventricle grew weaker and weaker till at last contraction almost ceased.

Under the influence of cesium chloride, faradization does not inhibit the cardiac contractility. In its physiological action cesium chloride only corresponds to potassium chloride in two respects: both obviate the delay in dilatation caused by calcium salts, and both increase the period of diminished excitability and so prevent tetanus from continuous faradization.

Experiments upon the Ears of Fishes, with reference to the Function of Equilibrium.—Dr. Henry Sewell (*Ibid.*), thinking that fishes were better fitted than any terrestrial animal for giving an experimental solution of the problem concerning the relation of the semicircular canals to the equilibrium sense, has performed over ninety experiments upon sharks and skates, removing different portions of the auditory tract and noting carefully the effects produced by the different operations. When, in a shark, either or all of the semicircular canals on one side only are cut through, the results are wholly negative—that is, the animal swims in the same manner as when uninjured. The same want of positive effect succeeds section of the two vertical canals on both sides, both in the shark and in the skate. Each of the six canals of both shark and skate has been individually severed, with uniformly negative results. In another shark, in addition to the foregoing operation, the canal of communication between the utricle and the sacculus was carefully cut open on each side without effect. By this procedure the sacculi, with the ampullæ of the anterior vertical and horizontal canals, were completely sundered as channels from the rest of the labyrinth. Laceration of the vestibular sacs and the removal of the otoliths from them was occasionally not productive of any change in the behavior of either shark or skate; but, on the other hand, the same treatment was often followed by quite definite results. On removing the otoliths on one side, there was usually a tendency to swim downward in a circle toward the side operated on, and, after the otoliths had been removed from both sides,

the animal dived downward and occasionally turned somersaults in a vertical plane.

When the sacculus is opened on one side there is an immediate tendency to dive more abruptly than usual, and to turn round the long axis of the body toward the injured side. When both sacculi are cut, the lateral motion becomes converted into a series of somersaults. When, in addition, the otoliths are drawn from each sacculus, the skate swims round and round in a vertical plane, in a circle two or three feet in diameter. This motion was sometimes continued for several days. When the ampullæ of the anterior, vertical, and horizontal canals were cut into or excised, disturbances of equilibrium were noticed in small sharks. The character of the movements is not simple, but apparently determined by an effort to swim in more than one plane at the same time. The large sharks seemed to suffer very slight disturbance of equilibrium even after severe lesions of the labyrinth.

Reflex effects upon the eyes and other organs were observed to follow irritation of the labyrinth. When the nerve attached to the ampulla was touched, active jerking of both eyes occurred. Slight mechanical irritation of the ampullæ had the same effect. Stimulation of the vestibular sacs, especially the removal of the otoliths from them, produced violent nystagmus. Irritation of the ampullæ and their nerves was frequently followed by vomiting.

Miscellany.

Water and its Impurities.—In an exceedingly interesting address before the Medical Society of the County of Schenectady, by the vice-president, Dr. H. V. Hull ("Medical Annals," Aug., 1884), we find the following:

"Water is greatly influenced by the nature and quality of the soil it passes through, irrespective of the mineral substances it may take up, and even rain water in its passage through the air from the clouds to the earth will absorb carbonic acid, ammonia and other salts, and will entangle with itself particles of soot from smoke, dust, and even minute germs floating in the air. In fact, rain water will usually contain two or three grains of solid matter in each gallon. River water, while it may be soft, is nearly always impregnated with decayed vegetable matter, and, if in thickly peopled districts, is quite apt to hold sewage in solution, which renders it highly dangerous to life and health. It is generally believed that our rivers may receive the contents of sewers, but, through the influence of plant and animal life, the water may undergo a complete chemical oxidation, and, in running water that has flowed ten or fifteen (some say but two or three) miles, all evidence of contamination may disappear. If this is true, it is a dangerous truth.

"Water may be clear, sparkling, and bright, and yet contain a large amount of impurity. The earthy salts which are so often found in solution in water are of no particular importance when compared with the organic matter which it may contain. The nearest approach to pure water is found in deep wells with rock bottom, situated a long distance from any source of contamination, and in streams of upland and uncultivated districts. For example, water which shows no deleterious substances on chemical or microscopical examination may still cause disease in those who use it. A suspected well was closed by a local board of health. The families who were inconvenienced by its closure demanded that they should either be allowed to use the water or else convincing proof should be furnished that the use of it was dangerous to health. The most carefully conducted chemical and microscopical examination gave a negative result. The board of health then made a house-to-house inspection, with the result of finding twenty-three cases of typhoid fever among two hundred and nineteen persons in families who habitually used the water from the suspected well. In the same portion of the town there were two hundred and seventy-one persons

who used other water, and among these persons there had been but ten cases of illness of any sort during that season, and of these diseases there were but two cases of typhoid fever. This report could lead to but one conclusion. After closing the well there were no more cases of typhoid fever in that neighborhood than in any other part of the town.

"This instance proves that nothing short of a physiological test, in the form of typhoid fever or some other zymotic disease, can convince the public that water may be clear and bright, have no unpleasant taste, and give almost a negative result on chemical examination, and at the same time be filthy and fatally poisonous.

"Water may present nothing offensive or unusual to the eye, may be clear and without sediment, and have a disagreeable or disgusting odor or taste, which a chemical or microscopical examination can not explain, and yet be used for domestic purposes without causing any noticeable increase of sickness.

"The sources of organic impurity are two—animal and vegetable, of which the former is far the more injurious.

"The use of water which has passed through swamps, and thus contains great quantities of vegetable matter, though not advisable without thorough filtration, is far preferable to the clear, sparkling water from a well contaminated by sewage. The stomach and bowels may be disturbed by swamp water, but there will not be those fatal results which attend sewage poisoning.

"During seasons of abundant rain, when the springs and wells are all filled, poisonous substances of all kinds are largely diluted, and are not so active in causing illness as in seasons of drought and low water, when whatever there is of poisonous substances in the water becomes more concentrated and thus more dangerous to life and health. In the autumn of 1881 a protracted drought was coincident with prevalence of typhoid fever in this locality."

The Purification of Water.—In the same address Dr. Hull said: "Without advocating the selection of confessedly impure waters and attempting to purify them, yet, under some circumstances, it is necessary to advise methods of purifying water. The chief methods adopted are distillation, boiling, subsidence, and filtration.

"Distillation is conversion of water into vapor and its recondensation by cooling, the impurities being left behind. The water by this means is produced in its purest state. It is, though bright to the eye, not palatable, but it is indispensable for chemical and medicinal purposes. On a large scale fresh water is now distilled from sea water for the use of ships, especially in long voyages.

"Boiling is requisite to destroy minute organisms and germs. From the researches of Dr. Dollinger and others we have proof that the thermal death point of most forms of bacteria is about 55° C. (120° F.), though some species have lived at a temperature somewhat above this point. After being boiled, the water should be exposed to the air for a time to absorb again a portion of oxygen and carbonic acid.

"Subsidence permits the settling down of impurities. By the exposure to air water is much softened, and the settling-bed thus serves two ends.

"Filtration is far the most important means, from a sanitary point of view, and is the favorite method for purifying water for use. Filtration is carried on on a very large scale by those water companies which supply large cities, and their filtering beds are elaborately prepared. Filtration on a small scale is now the rule in most well-regulated households, and private manipulation is not usually superfluous with the best water supplied by any company. The chief materials used in the construction of filters for private families are animal charcoal, silicated carbon, carbide of iron, spongy iron, and sand. Vegetable charcoal is also used to some extent, especially in the construction of cheap filters for domestic use. It is not considered so good a material for this purpose as animal charcoal, as the latter greatly exceeds the former in its power as a disinfectant. When animal charcoal is used, it must be specially prepared and well burned. If any of the animal matter be left in it, it becomes (as shown by a report of the London River Pollution Commissioners) a breeding place for myriads of small worms, which pass into the water. With the other materials mentioned as are made of burnt shale, or, as is the case with the carbide of iron, taken from the interior of blast furnaces, there is, of course, no risk of this.

"Of all forms of domestic filter the glass decanter with a solid carbon or silicated carbon block seems to answer most of the requirements of an efficient, uncomplicated filter for family use. It has also the great advantage that every part of it can be seen, so that it can be kept scrupulously clean. These filters go on working perfectly well for a very long time, requiring scarcely any care beyond cleansing the surface of the block of carbon occasionally with a hard brush. Filters, however, like most things, will not go on working for ever, and attention from time to time is necessary. Says a distinguished authority on this matter: 'All filters, after a time, become clogged up, and have, therefore, to be taken to pieces and thoroughly cleaned; or, if this can not easily be done, they may be purified by passing through them a strong solution of potassium permanganate, with the addition of a few drops of strong sulphuric acid, and afterward two or three gallons of pure or distilled water, acidulated with hydrochloric acid. The charcoal in a filter may also be purified, to a certain extent, by exposing it for some time to the sun and air or by heating it in an oven or furnace'; though it is always far the better plan to replace the old charcoal with that which has been freshly burned. In case of a cistern which is built so as to allow all the water it receives to pass through a filtering medium, the material of which the filter is composed—usually pebbles, sand, and charcoal—should be taken out, the pebbles and sand well washed, and the charcoal replaced by some which is fresh. This should be done certainly as often as every two or three years, and the cistern ought to be built in such a manner that this may be done easily.

"At Antwerp, the turbid, polluted water of the river Nethe is 'rendered colorless, bright, palatable, and fit for dietetic and domestic uses' by filtration through spongy iron, and it is the opinion of no less an authority on the subject of water analysis than Professor Frankland that specific living germs are destroyed by this process. This shows conclusively the remarkable power which is possessed by spongy iron to purify polluted water, and perhaps may be taken as an answer to the question of whether it is possible to so improve a suspicious water supply, employed from necessity, as to remove the danger."

The Hygiene of Small Towns.—At a recent meeting of the Kentucky State Sanitary Council, Dr. J. N. McCormack, of Bowling Green, read a paper on this subject, and in the discussion Dr. Dudley S. Reynolds, of Louisville, said: "This is not alone a question as to what shall be done with kitchen slops and human excrements, but equally one of the medium through which the diseases called filth diseases find their way into the system. The people of small towns depend for their water-supply upon wells, springs, and cisterns. It is in those places where spring water is in most common use that cerebro-spinal fever and typhoid disease most frequently occur.

"Sydenham strikes the real cause of the plague that devastated London in 1665-'66 when he explains the character of the drainage and the accumulations of filth that had saturated the soil. His representations correspond exactly with what was observed at Memphis at the time the yellow fever swept away almost the entire resident population of that unfortunate city. It was not believed that Memphis could ever again rise to any importance as a commercial city.

"Colonel Waring, however, devised a system of drainage for Memphis, and took the precautions to make arrangements to prevent the evils of accumulated and decaying filth. It is now no longer looked upon as a fatal spot. Small towns, however, can not afford to build these sewers, and the most effective way that suggests itself to my mind to promote the cleanliness of small towns and avoid accumulations of filth is by legislative enactment, placing the responsibility upon local boards of health in connection with trustees and town councils."

In regard to the filtering of water in cisterns, Dr. Reynolds said: "The great object of sanitation is to prevent the introduction of contaminating material into the system. If a cistern is properly constructed, and the water from roofs properly collected, not permitting the cistern to receive one particle of the first water that falls, and that washes the roofs of houses which collect it, we can conceive how it will be comparatively pure when in the cistern. Some importance, however, should be attached to the means employed to get the water out when once it is properly stored there. Pumps should not reach to the bottom of cisterns, for, when they do, the water drawn each time must be drawn

through the sediment of it all. No matter what system of filtering or straining is employed, poisons, in the form of gas and microscopical bodies, will exist within it. Gases are even more penetrating than microscopical particles."

The Illinois School-Vaccination Order.—The "Fifth Annual Report of the State Board of Health of Illinois," although dated January, 1888, and covering the year 1887, has but lately reached us. It is a volume of more than six hundred pages, consisting largely of tabular matter, and reflects the greatest credit on the industry and carefulness of the board's secretary, Dr. John H. Rauch. It deals chiefly with the work of the board in administering the Medical Practice Act, and with the subject of small-pox and vaccination. Among the great mass of interesting matter given in connection with the latter we find the following:

"Of the total number of enrolled scholars in Illinois in the autumn of 1881, returns and other data in the office of the State Board of Health indicate that considerably less than one half (45.34 per cent.) were protected against small-pox at the date when the vaccination order was issued, requiring children to present satisfactory evidence of proper and successful vaccination before being admitted to the public schools after January 1, 1882.

"Within sixty days thereafter—that is, before the last of February, 1882—nearly 93 per cent. (92.92) of all those in attendance in the State at large had presented this evidence; and, of the remaining fraction, 1.2 per cent. had presented evidence of protection by previous attack of small-pox, or of apparent insusceptibility by repeated unsuccessful vaccination. So that the ratio of protected school children was more than doubled within a few weeks—increased from 45 per cent. to 94 per cent. of all those in attendance.

"These figures, indeed, understate the work accomplished in this brief period, since they do not include over 20 per cent. of revaccinations performed after December 1, 1881. As more than two thirds of these revaccinations proved successful—thus demonstrating the renewed susceptibility of that number—this proportion ($20.88 \times .678 = 14.15$) should be deducted from the 45.34 per cent. classified as protected by vaccination before the date of the order. This would then show that, on the one hand, 68.81 per cent., or more than two thirds of the entire public-school population of Illinois, was susceptible to small-pox on the 1st of December, 1881; and that, on the other hand, there was less than 6 per cent. of unprotected and susceptible remaining among those actually in attendance on the 1st of March, 1882. In other words, that the vaccinal protection of 450,000 public-school children, in round numbers, had been secured within sixty days.

"The foregoing proportions are based upon the returns of 304,586 individual scholars, whose names, ages, sexes, and vaccinal history were forwarded to the State board."

Quarantine between States.—At the recent conference of representatives of the State boards of health of the Gulf States the following resolutions were adopted unanimously:

"Resolved, That there should be an entire harmony and co-operation between the health authorities of the several States.

"Resolved, Every State shall appoint inspectors on all passenger-trains from infected places, and on all steamboats or other river craft on which it may be deemed advisable to have inspectors, to see that the quarantine rules are enforced in good faith.

"Resolved, Every State should have the right to place inspectors of its own at points within the jurisdiction of any other State, and upon railroad trains and river boats within the limits of such jurisdiction. Inspectors coming under this head should be allowed all reasonable facilities for obtaining information and for the transmission of the same, and should comply with the quarantine regulations of the State or locality in which they are acting.

"As to local or municipal quarantine: yellow fever or cholera having been introduced into any community, particularly into any city or town, earnest efforts should be made to confine the disease within the smallest limits, that is to say, to prevent its dissemination through the community. To this end the infected house or locality should be rigorously isolated, and disinfection should be employed according to the most improved methods."

Original Communications.

REMOTE PUERPERAL HÆMORRHAGE.*

By T. GAILLARD THOMAS, M. D.,

CLINICAL PROFESSOR OF MEDICINE IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

SINCE I last attended a meeting of the society I have met with two cases which have suggested to my mind the considerations which form the basis of what I am about to say. I refer to a form of hæmorrhage which comes on three weeks or a month after labor, after the physician has ceased making his visits. Some years ago the late Dr. McClintock, of Dublin, wrote a paper on this subject, and called it "remote or delayed puerperal hæmorrhage," and Dr. Mundé has recently written an article bearing upon the same point, published in the "American Journal of Obstetrics." I have seen a good many of these cases, and the history of one which I will relate illustrates the experience that I have had with most of them.

In such a case the uterus may have contracted after labor, and everything have gone on properly until the ninth day, when the physician has ceased to make his daily visits, but from that time the woman begins to lose blood steadily. If she makes a little unusual effort, or if anything occurs in the family to cause considerable mental excitement, an exceedingly dangerous hæmorrhage may take place, which will require to be checked with the tampon. If sudden and profuse hæmorrhage does not occur, demanding the services of a physician immediately, a steady loss of blood in moderate amount may continue for a week or ten days, until the woman becomes very much exhausted.

The particular case of which I have had the history in mind in the foregoing remarks was that of a lady to whom I was called in consultation by a German physician of considerable experience. Ten months before, the patient had called at my office, and had given a somewhat peculiar history. She had been married for several years, her husband was a vigorous, healthy man in every respect, and she a remarkably handsome and well-formed woman; and yet no intercourse had ever occurred. On examination, it was found that she was suffering from a very aggravated form of vaginismus. Her husband had exhausted all his efforts, and her mental state had become such that she could not entertain the thought of sexual intercourse. An operation was performed, at the end of a month the patient left the hospital, and just nine months later she was delivered of a child. About the end of the seventh month of gestation the veins leading from each labium majus became greatly enlarged, and the parts presented the appearance of a mass of earth-worms of the size of one's fist. I had seen the condition in so marked a degree but once or twice before.

On the ninth day after delivery hæmorrhage occurred, and she sent for her physician, who used all the ordinary means, including ergot, tannic acid, dilute sulphuric acid, etc., for stopping it, but without avail. The tampon, however, was not resorted to. About three weeks after her delivery the patient

was seized with very profuse and violent hæmorrhage, which reduced her very much. It came on after she had got out of bed. When her physician reached her the hæmorrhage had ceased. Each time it had begun with the passage of a large blood-clot. On this occasion I was consulted, and I visited the patient three days later—the next time that hæmorrhage occurred. I took with me a nurse and instruments for dilating the uterine canal and for removing the remains of membranes. Her physician, however, felt very positive that none of the membranes had been left in the uterus, and stated that he had examined the placenta very carefully, and that there was no interruption of its continuity whatever. But I felt equally positive that some of the placenta yet remained in the uterus.

When the patient had been placed on the table and the ether-cone had been applied over her mouth, she suddenly sprang up in a state of wild excitement, and could not be induced to continue the inhalation of the ether, it had affected her so badly when she was operated upon for vaginismus. All means of persuasion were futile, and her friends desired that she should be compelled to take the anæsthetic. But I objected to compulsion, because, under such circumstances, after delivery, I have seen most violent and uncontrollable mania developed. In one instance the mania continued three weeks, during which time the patient was very violent, and had to be watched constantly by a nurse. It is true, the mania seemed to be of an hysterical nature, but, nevertheless, it was very violent. I think we can not be too careful as to doing that which is strongly opposed to the will of a puerperal woman. I would rather have run the risk of a violent hæmorrhage in this case than have forced the patient to take the ether. She was spoken to kindly and put back into bed, and I assured her husband that she would send for me again within twenty-four hours, to have the operation done.

I was sent for the next day. The patient was then etherized, the uterine canal was dilated, the curette was passed, and three pieces of placenta were removed, each as large as the last phalax of one's index-finger. Very little hæmorrhage was excited by the operation, and I felt that in removing the pieces of placenta I had removed the cause of the hæmorrhage.

The points I wish to make are these. The case was an interesting one: 1, with regard to the vaginismus; 2, with reference to the condition of the veins of the vulva; 3, with reference to the great danger of giving ether during a state of maniacal excitement; 4, with reference to what I believe to be the usual cause of delayed puerperal hæmorrhage and the proper means for its cure.

With regard to the statement, so often made, that the placenta has been examined carefully and found entire, it usually amounts to nothing. In the first place, we know that the physician commonly looks at the after-birth hastily and in a careless manner. Besides, I believe that little pieces may be broken off and remain behind, which no man could recognize from an examination of the placenta, though he examined it with the utmost care. As in this case, so in all others of delayed puerperal hæmorrhage that I have met with, it has been due to retained placenta or membranes. Dr. McClintock mentioned a case in his practice which, I believe, proved fatal. I have met with some which very nearly proved fatal, and doubtless some of those present have encountered similar cases.

* Remarks made before the New York Obstetrical Society, April 15, 1884.

SOME RECENT ADVANCES IN METHODS OF WOUND TREATMENT.*

BY LEWIS S. PILCHER, M. D.,
BROOKLYN.

RATIONAL methods of treatment command permanent acceptance according to the perfection with which they carry out recognized principles. All the advances in the treatment of wounds which the present day is witnessing are based upon the one idea that the essential agents by which disturbances in the healing of wounds are excited are minute organisms, the germs of which are conveyed from without, either by the body that produces the wound, or from the air that gains access to it, or from something that comes in contact with it, whether it be the hands of the person that binds up the wound, or the appliances that he may use. The methods and appliances, therefore, which I wish to call attention to at this time depend for their merit either on their power of excluding such micro-organisms, or of limiting their activity, as in the case of the materials for dressings to be described, or on the facility with which they may be prevented from becoming the carriers of contamination, as in the case of the instruments and appliances. What I have to say will be arranged under the three heads of

1. Aseptic instruments.
2. Buried or layer sutures.
3. Absorbent dressings.

1. *Aseptic Instruments.*—From the standpoint of a possible sepsis, every joint, every roughness, every crevice, or angle, or absorbent surface about an instrument, is a source of danger. As example, take an ordinary torsion forceps, or needle forceps, and note the places for the lodgment of impurities underneath the catches, and slides, and springs, and in the crevices of the joint—places into which it is impossible to reach for even the purposes of ordinary cleanliness. The fashion of roughening the handles of scalpels and other instruments to give the fingers of the surgeon a more secure hold; even the stamping upon instruments the name of the maker—these produce objectionable depressions that make absolute cleanliness more difficult. The appreciation of the importance of these considerations is creating a new standard for instruments, which is characterized by the utmost simplicity of model, and plainness and smoothness of finish. The manufacture of instruments out of a single piece of metal, without joint or seam of any kind, is the highest type of this new standard. Where joints are unavoidable, the adoption, whenever possible, of the French joint, as it is called, which permits the parts to be easily unjointed and separated for purposes of cleansing, is another feature of this new standard. Already in the instrument-shops are beginning to appear instruments in the manufacture of which these considerations have been regarded. The instrument-makers of Germany have taken the lead in this direction, this being the natural outcome of the scientific precision which marks the work of the surgeons of that

nationality in their precautions against septic contamination of the wounds they make or have to deal with.

As an illustration of the possibility of applying these principles to comparatively complicated instruments, take the case of the "Russian" needle-holder, which, in its original model, notwithstanding its convenience in use, merits all the objections that have earlier been urged against instruments that can not be perfectly cleaned. Yet, in this modified instrument which I show you, and which has been constructed at my suggestion by Mr. Pfarre, of Tiemann & Co., all its objectionable features have been overcome, while it still remains practically the same instrument. One of its most objectionable features—the spring between the shanks of the handles, that was designed to automatically separate them—has been dropped as practically superfluous. The handles are of smooth vulcanized rubber, and, having been baked upon the metal in the course of manufacture, present neither crevice nor joint, and are so intimately incorporated with the metal portion of the instrument as to form practically a single piece. The catch is made so that it can be detached by a few turns of a thumb-screw, by which it is held in place, and, finally, the blades are joined by the "French joint," already alluded to, which permits them to be readily separated from each other. Thus the instrument can be easily and quickly taken apart, and the most perfect cleansing of every portion readily accomplished. One objection is to be made, however, to this particular instrument, and that is the fact that the manufacturer's name has been stamped on it. This creates an unnecessary source of trouble in the cleansing, which might properly be objected to by the scrupulous surgeon.

Let me call your attention to one more instrument illustrating this phase of the subject. Note the construction of so common and simple an instrument as the ordinary anatomical or dressing forceps. The two pieces that constitute the blades are welded together, so that the approaching blades form a very acute angle, into the apex of which it is exceedingly difficult, nay, even impossible, to reach with anything to cleanse it, and in the usual attempts at cleansing the instrument there is always left a region where more or less objectionable material necessarily remains. In addition, the outer surfaces of the blades are generally roughened, in order to give the surgeon a firmer hold and better control of the instrument. But here I present a pair of anatomical forceps which, by one or two apparently trivial modifications, is freed from the objections noted. The acute angle has been filled up with a bit of metal, welded into its place, and the surface which it presents between the divergent blades can be readily reached and thoroughly cleaned. Then the roughening of the blades has been done away with, and a smooth and polished surface everywhere secured, except at the tips of the blades, where a certain amount of serration is required to give the forceps a sure grip upon the tissues it may seize.

As examples of the class of instruments which have been described, and which I have termed "aseptic," I present for examination a large variety, including different models of hæmostatic forceps, hook-retractors, sharp spoons or curettes, scalpels, dressing-forceps, amputating-knives and saws,

* Remarks made before the Medical Society of the County of Kings, July 15, 1884.

chisels, gouges, drills, etc. These are all either made from one piece of metal, or have had their parts soldered together so as to leave no crevice, angle, or depression for the retention of septic matter. These are samples from quite a number of different German instrument-makers.

Of like excellence, from the standpoint of asepticity, is another series of instruments, which I also present for examination, in which, as in the case of the needle-holder already shown, the handles are made of smooth and polished hard rubber, the rubber having become intimately incorporated with the metallic part of the instrument by having been baked upon it in the process of vulcanization. These have been made by Tiemann & Co., at the suggestion of Professor J. A. Wyeth. The result of the attempt has been to produce a very handsome and serviceable as well as "aseptic" class of instruments, the handles of which have the additional merit of being light and not corrodable.

In connection with these instruments, the cases in which they may be kept are worthy of attention. The general considerations, which have been alluded to, that make it important to banish everything in connection with surgical instruments that may harbor dust or resist easy cleansing, will urge us to throw aside the elaborate velvet- and plush-lined cases in which instruments have been wont to be placed, and to replace them with cases of the simplest construction, with racks of metal or polished wood for the support of the instruments. Samples of such cases, which I herewith present, show that, as regards looks, they may be quite the equal of the old styles.

2. Buried or Layer Sutures.—By this term is meant the application of a separate series of sutures to the deeper layers of tissue that may have been involved in a wound. By the use of as many successive layers of such sutures as may be required, all the parts of a wound, however deep, may be brought into absolute and secure apposition, and thus rapid and immediate healing be favored, from the bottom to the surface, as readily as if it had been only a slight superficial wound. As the wound is closed by the successive apposition of one layer of tissue after another, each series of sutures becomes buried, and receives no further attention, being left to the due activity of the tissues for removal by absorption. This buried or layer suture requires for its safe use a reliable article of catgut—one that the surgeon may be sure never to hear from again by reason of any irritation produced by it after it has been covered up from sight. Such a catgut can be very readily and quickly prepared from any ordinarily fair specimen of gut by immersing it in a watery solution of corrosive sublimate (1-1,000) for forty-eight hours, and afterward keeping it in an alcoholic solution of the sublimate of like strength until it is required for use.

This method of using sutures is a natural development from their use as ligatures, in which case it has become the habit to cut the threads off short and abandon (that is, bury) them in the tissues when the external wound is closed. The earlier employment of the buried suture was in attempts at the radical cure of hernia, and in certain plastic operations, as the repair of extensive perineal lacerations. It has lately been extended to securing deep apposition of the flaps made

in major amputations, and is susceptible of being applied to many deep fresh wounds. It is a most valuable device for preventing the occurrence of deep cavities in which wound secretions might accumulate. Still, for its safe and successful use, without the accessory aid of drainage-tubes, considerable experience and judgment are required; indeed, for the general practitioner, I should say that the free use of drainage-tubes ought not to be dispensed with, even though the buried sutures were employed.

3. Absorbent Dressings.—In the practical application of antiseptic methods there is no point which is of greater importance than to secure, as an external covering to the wound, some material that shall readily and perfectly soak up whatever discharges may appear upon the surface. The proper apposition of the wound-surfaces having been accomplished, and adequate provision for the escape of the secretions having been made, the next thing is to provide absorbent materials for the external dressings, which themselves must be purified from any matter that might contaminate the wound. The use of carbolated gauze for this purpose is familiar to all as a part of the dressing introduced by Lister. But the eightfold dressing of Lister is quickly soaked through, so that it must be covered with a layer of Macintosh to compel the diffusion of the secretions horizontally over its area, as well as to prevent the escape of the carbolic acid. Saturated as it already is with a solution of resin, it is only the interstices between its fibers that hold the secretions by the power of capillary attraction. It is difficult to prepare, it is expensive, it needs frequent changing, and it so rapidly loses its carbolic acid that it must have been quite recently made to be reliable. For these reasons substitutes for it are greatly needed—indeed, are imperative—if the best results in the treatment of wounds are to be made attainable by general practitioners. With the lapse of time, as the result of much experimenting, it has become apparent that the one great essential in a wound-dressing is its absorbing power. The first important contribution in this direction was the accidental discovery of the value of peat-mold as a wound-dressing by Esmarch in his clinic at Kiel—a discovery which has been followed up with energy by this surgeon and his assistants to the full development of their system of permanent dressings, in which absorbent materials, not necessarily peat-mold, form an essential part. Of the materials which have been used with advantage as absorbent dressings, there are two which, by reason of the energy of their action as absorbents, their cheapness and general availability, and the simplicity of their use, I desire to especially dwell upon in this connection; these are turf-moss and sawdust.

Turf-Moss.—This is the ordinary turf- or marsh-moss, growing in all temperate climates in damp and low places, and especially familiar to us from its use by florists as a bed in which to thrust the stems of flowers and plants, and by nurserymen as a packing about the roots of shrubs and saplings that are to be transported some distance. It answers these purposes by reason of its power of sucking up and retaining moisture. The *Sphagnaceæ*, or turf-mosses, of which there are a number of varieties, have their stems and leaves of a cellular and reticulated structure; a comparatively small

proportion of the cells and spaces entering into their structure are filled with chlorophyll, the greater part of them being empty in the dry state, but rapidly sucking up and swelling out with fluid when brought in contact with moisture, the rapidity of this filling with fluid being facilitated by the existence of numerous perforations, communicating with the external air, that exist in the walls of the cells. This absorbing power eminently fits it for use as a wound-dressing. For this purpose, having been gathered and sorted over to free it from perceptible impurities, it is dried, and is then ready for use. It may be used either in the natural state or after having been first impregnated with some antiseptic, as corrosive sublimate or naphthalin. Unless this latter is done, the moss is likely to develop an unpleasant smell after it has been kept applied to a wound for a week or so. To Leisrink, of Hamburg, is due the credit of having introduced the use of this material, which he did in a communication to the "Berliner klinische Wochenschrift" in the fall of 1882. In the spring of 1883 it was made the subject of a communication to the German Surgical Congress by Hagedorn, of Magdeburg, and at the present time it is almost exclusively used as a wound-dressing in some of the largest clinics of Germany. It is used, made up into pads or cushions of various sizes, by inclosing the dried and prepared moss in bags of coarse gauze, smaller and softer pads, made out of the partly pulverized particles, being used to place directly upon the line of the wound, while larger cushions are applied over these so as to cover an area some distance in every direction from the wound, and, in the case of the limbs, quite encircling them. It answers admirably for purposes of protection and compression by means of its softness and elasticity, as well as for the main object of absorption. I consider it a most valuable addition to the list of wound-dressings, and one which deserves to become popularized in the United States.

Sawdust.—In this cheap and despised material we have likewise a very superior substance for making absorbent wound-dressings. Compared with the other wood preparations that have been introduced—i. e., wood-wool and wood-flour—I think it is to be preferred, for it is practically as absorbent, and is much cheaper and more readily obtained. The fact that as an absorbent it answers all practical purposes, while it can always be obtained, and with little or no expense, leads me to think that it is destined to become the most universally used of all dressing materials in general practice. There was a hope that in absorbent cotton a most desirable and generally available agent for wound-dressings had been found, particularly as it was easily impregnated with various antiseptic substances, but, although unequaled as a protective and compressing agent, it has failed as an absorbent material. My observation is that only a limited layer of the cotton, immediately adjacent to the wound, absorbs, and that this quickly forms a crust which retains the discharges beneath it, or prevents their further escape from the wound. In this way I have been repeatedly disappointed in its use, and balked in my efforts at the drainage of wounds. For this reason I would reject it altogether as an immediate dressing, and reserve it only for external protective purposes. But even here it can be supplanted by

quilted cushions of sawdust at a tithe of the cost. The dust obtained from soft and absorbent woods, as white pine, poplar, or basswood, is desirable if it can be obtained. It should be quite fine, and, if necessary, should be passed through a sieve to separate the coarser particles. It absorbs more readily and evenly if it is a little moist when applied, and for ordinary purposes it may be moistened to advantage with a dilute solution of corrosive sublimate, 1 to 1,000, at the time of using. The corrosive sublimate, of course, soon decomposes when thus mixed with the sawdust, and can not be depended on for maintaining a prolonged aseptic condition of the dressing. For this reason a sawdust dressing, if long retained, after becoming in some degree filled with wound-secretions, will become sour and smell unpleasantly. This may be obviated by mixing in with the sawdust, already dampened with the corrosive sublimate, a small amount of naphthalin, and a dressing so prepared may be retained for a prolonged period without becoming a source of danger or offense.

The sawdust is to be made up into pads or cushions with purified and absorbent gauze. This prepared gauze is simply the ordinary cheese-cloth of the shops, which has been boiled in a dilute solution of caustic soda or of potash for several hours, then repeatedly rinsed, and finally dried. This should finally be immersed for a few minutes in the corrosive-sublimate solution before it is used. With these means pads and cushions of any size may be made from two inches to half a yard square, having a general thickness of about one inch, the sawdust being prevented from shifting by occasional through-and-through stitching or quilting with thread.

Here is a little packet which I have received from Professor Esmarch. It is a sample of what is known as his "first dressing for the wounded on the battle-field." A word on the subject of the treatment of gunshot wounds before I show it. During late years the dangers of meddlesome interference in the case of gunshot wounds have become well understood. It must be accepted as a settled canon of practice of the surgery of to-day that in the case of such wounds immediate disinfection of the apertures of entrance and of exit, if such exist, shall be accomplished, if possible, and that there be no further interference until those symptoms arise that indicate a necessity for it, or until the surroundings admit of the most exact antiseptic precautions being taken throughout, whatever interference is attempted. All probing, therefore, of a bullet track at the beginning of its history is to be esteemed an infraction of good surgery. To provide for the proper immediate dressing of a gunshot wound, Esmarch would have every soldier provided with one of these little packets and instructed in its use. His packet, as originally devised, consisted of a triangular bandage or handkerchief, a long, narrow bandage, folded, with safety-pins for fastening them, and two tampons made of salicylic jute, inclosed in salicylic gauze, the whole protected in an envelope of parchment-paper. But of late, as seen in this sample, the jute of the tampons has been replaced by sawdust which has been treated with corrosive sublimate. I show it here as an example of the use to which sawdust is being put in the matter of wound-dressings,

In conclusion, by way of practical illustration of what may be accomplished by consistent antiseptics, I desire to present for your examination this young man, who, on the 4th of July last, accidentally thrust his arm through a glass door and received thereby a deeply penetrating wound at the junction of the upper and middle forearm. The wound was transverse to the axis of the forearm, and completely severed the belly of the flexor carpi radialis muscle, wounding also the pronator radii teres, and opening up the deep intermuscular spaces, but without injury to any large blood-vessel. He was seen immediately by a neighboring physician, who, as there was then no hæmorrhage, dressed the wound by several points of suture through the skin, and by a firm bandage to the forearm. In the course of the night a general hæmorrhagic oozing from the wound-surfaces began; the stitches that closed the wound externally held firmly, and the blood, denied exit, infiltrated the intermuscular spaces, causing the whole forearm to become greatly swollen, the infiltration extending on the inner side of the arm half way up to the shoulder. The next morning I saw him, and reopened the wound by cutting the sutures that had been applied, and, in addition, enlarged the wound by a long incision down the axis of the forearm from the middle of the original wound. The clots with which the parts were infiltrated were turned out and cleared away as perfectly as possible by scraping with a sharp spoon. A thorough irrigation with a solution of corrosive sublimate, 1-1,250, was then made, the wound was packed with iodoform gauze, and a compress and bandage were applied over all. This dressing was hardly completed before it became evident that there was a peculiar hæmorrhagic condition present in this wound, for through the dressings that had been applied quite a free oozing of thin bloody fluid quickly appeared, and was so marked that I thought best to remove the dressings, and reapply them after a few moments' exposure of the interior of the wound to the air. I then packed it with a purified sponge, thrusting this thoroughly down into the crevices of the deeper parts of the wound, and over this I again applied a tampon of iodoform gauze supported by a bandage. Still the oozing of bloody fluid, percolating through these dressings, continued to such an extent that I did not think it safe to leave it, and, after waiting a few moments, I again removed all the dressings that had been applied and exposed the wound. The bleeding was a general oozing; there was no tendency to coagulation manifested by the blood. At a number of points I now applied catgut ligatures, inclosing small masses of the tissues where the oozing was most profuse, applying also compresses wrung out in quite hot water. Still the oozing was only partially stanchd; I then packed the wound with two sponges, coupled with the iodoform tampon and the compress and bandages as before. By these means the hæmorrhage was finally controlled in great measure, although during the following night there was considerable oozing of bloody serum through these dressings, but no positive hæmorrhage. For two days the dressings were left undisturbed. At the close of the third day I determined to remove the tampons and bring the parts into apposition as far as might be possible. Upon removing the external dressings, I found that already an active process of granula-

tion had been set up, and that the new granulation material had so extended itself into the interstices of the sponges that the sponges could not be removed without tearing the adhesions thus formed. This produced a slight bleeding, which at once ceased spontaneously. The wound was then irrigated with the corrosive-sublimate solution, the wound surfaces were brought together by sutures deeply inserted, and a drainage-tube was inserted to the bottom of the deepest part of the wound cavity. Over all was placed a cushion of sawdust moistened with the corrosive-sublimate solution. On the two following days the saturation of this pad with serous discharges was so marked that each day a new pad was substituted, irrigation of the wound and of the adjacent surfaces being carefully attended to each time. On the third day the drainage-tube was removed and a new pad applied, and on the following day also a fresh pad was applied. This last dressing was made four days ago, and it has not been disturbed since.

It is now the twelfth day since the infliction of the injury, and up to the present time there has been no suppuration from the wound, the discharges having been purely serous. None of the ordinary signs of inflammation have been visible about the wound; but, from the time that it was enlarged, cleared of its clots, and the hæmorrhage checked, its condition has been one of progressive well-being, and this notwithstanding a combination of conditions that afforded good grounds for the gravest apprehensions as to possible diffuse phlegmonous inflammation and prolonged suppuration and tedious recovery.

If you will indulge me, I will now remove the dressings and submit the wound to your inspection. The parts being now exposed, there is seen a T-shaped wound of the forearm nearly healed, and its borders presenting a soft and healthy appearance. Upon the lower surface of the pad that was removed a few drops of pus are discernible. There are no secretions upon the surface of the wound. The ecchymotic condition of the subcutaneous tissues of the forearm and of the lower inner half of the arm is still very marked. [After the patient had been inspected by the members of the society, the wound was irrigated with a solution of corrosive sublimate, and again covered with a sawdust pad. The after-progress of the case to complete recovery was rapid and without accident.]

PERMANENT UNILATERAL PARALYSIS

OF THE

LARYNGEAL ABDUCTORS

FOLLOWING CEREBRAL EMBOLISM:

A UNIQUE CASE.*

By D. BRYSON DELAVAN, M.D.,
NEW YORK.

In presenting the history of the case indicated in the title of this report the intention was to bring it before you, not alone on account of its extreme rarity and of the interest which always attends any scientific novelty, but more

* Read before the American Laryngological Association, May 13, 1884.

particularly because it seemed to represent an excuse for a renewal of the much-worn discussion as to the question of abductor paralysis in general, and as well to extend the allurements of a possible clew to some of the hidden mysteries of that most unintelligible condition.

A review of the literature of abductor paralysis, however, has quickly recalled the fact that we are to-day in as much uncertainty and doubt regarding many points in its pathology as ever, and we are forced to recognize that, with our present want of light, a case presenting the features of the one at hand is apparently beyond the possibility of certain and definite explanation. It is offered, therefore, as the simple relation of a curious fact, which, in the interest of scientific progress, should be added to the already existing knowledge of the subject, in the hope that accumulation of information may some day result in a full solution of the problems with which it is associated, and as the beginning of further research in the same direction. The following is the history of the case. As to its infrequency, Nothnagel, in his article on Cerebral Hæmorrhage, in von Ziemssen's "Encyclopedia," vol. xii, p. 116, says: "Unilateral paralysis of the vocal cords or of the pharynx are exceedingly rare," while under the head of cerebral embolism it is not alluded to.

Mr. W., aged sixty-nine years, American, widower, retired merchant. Family history in the main excellent, the patient coming of a stock remarkably long-lived and sturdy, but affording evidence in some of its branches of the tuberculous and the rheumatic diatheses. Patient has been a man of splendid physique and strong constitution, of regular habits, and strictly temperate in the use of alcoholics, but immoderately addicted to tobacco. Since middle life has suffered greatly from rheumatism, and has rapidly accumulated fat, but gives no history or indication of any other diathesis. He is right-handed. In 1876 he had an attack attended with vertigo, partial insensibility, and numbness, but without any distinct paralysis.

On December 18, 1877, he was again attacked, this time with a well-marked apoplectic seizure. Although complete insensibility was at no time present, there was intense pain in the back of the head, and in the nose on the left side, numbness and impairment of motion of the left arm, side, and leg, almost total inability to swallow, and, finally, a remarkable change in the quality of the voice, which, from having been full, deep, and sonorous, was reduced to a cracked, piping, and uncertain tone, which rendered its use almost impossible. Articulation was also impaired, the patient for months afterward being obliged to pronounce each syllable separately, speaking slowly and with difficulty. There was at no time, nor to any degree, aphasia. There was distinct ptosis, with paralysis of the left side of the face and tongue.

After continuing for two or three days, the general symptoms began to subside, and a slow but pretty steady improvement continued for many months, with regard to all except the voice, the leg first regaining its normal condition, then the arm, and, finally, the face. In the voice, however, there was little apparent change for some time, but by degrees it became more readily controlled and less discordant, although the high-pitched quality has persisted up to the present time, together with loss of phonating power.

In 1882 permission was given to examine the larynx, when it was at once made evident that there was a complete paralysis of the left vocal band, the position of which was in the median line.

The larynx was remarkably easy of demonstration, and the diagnosis was afterward confirmed by my friend, Dr. Clifton Wagner, who kindly consented to examine the case in consultation.

Laryngoscopic examinations, made at intervals subsequent to 1882, have demonstrated no change in the position of the cord. To summarize briefly; in a case of apoplexy, due, evidently, to embolism of the middle cerebral artery, in which paralysis in the region of the pharynx and larynx was especially well marked, all of the paralytic symptoms have almost entirely disappeared except those relating to one set of muscles—namely, the laryngeal abductors of the affected side—and these have continued paralyzed, without any apparent change, for a period of seven years.

From the foregoing record it is evident that the origin of the laryngeal paralysis, together with that of the other muscular groups, was central. Simultaneously with the attack of hemiplegia the voice was lost. Consequently, the causes of both were probably identical. In other words, a lesion occurring in one and the same region of the brain was responsible for both. The diagnosis of cerebral embolism or endarteritis is based, with justice, upon the gradual onset of the attack, the absence of complete unconsciousness, and the steady disappearance of the hemiplegia, together with the fact that the patient has since had slight attacks of vertigo, with numbness, heat, and formication of the side first affected. From the seat of the paralysis resulting from the principal attack, it is more than probable that the middle cerebral artery was the vessel affected. We have, therefore, embolism, anemia of certain brain-centers, gradual re-establishment of the circulation, with corresponding disappearance of the paralytic symptoms, and, finally, permanent paralysis of the most important, and by far the most active, set of muscles in the larynx. Admitting the possible existence of a ganglionic center for the larynx, the results above described may be explained upon the basis of one of the three following propositions:

I. That broadly formulated by Semon—namely, that "there is a proclivity of the abductor fibers of the recurrent nerve to succumb to pathological influences affecting the roots and trunks of the motor nerves of the larynx."

II. That there is an inherent tendency in the cerebral motor center for the larynx to degenerative processes from which the neighboring parts of the brain are exempt.

III. That the ceaseless activity of the abductors is maintained by the expenditure of an amount of nervous energy greatly in excess of that required to stimulate the opposing muscular group—i. e., the adductors—so that a central lesion, sufficient merely to weaken the energizing power of the neighboring centers, might result in a virtual paralysis of the abductors, sufficient force not being left them to oppose their fellows of the opposite group.

The explanation of the present case will probably be found to lie within the limits of the two last propositions, and to be based upon the following ground: Compensation for the nutrition withdrawn by occlusion of the affected artery was established by the development of the collateral circulation of the region to an extent sufficient to furnish a supply of nervous energy adequate to all ordinary demands, except in the case of the abductors, in which, the demand being

excessive, the diminished nerve-supply failed to furnish a stimulus capable of enabling them to maintain their normal relation of adductor opposition, and thus producing the feebleness, irregularity, and uncertainty of tone observed in the voice, and, laryngoscopically, the position of the vocal band as in abductor paralysis. It is not impossible, moreover, that the special tendency of the laryngeal center to degenerative changes may be due to some distinct peculiarity in the distribution of the arterial branches supplying the part.

1 EAST THIRTY-THIRD STREET.

DISCUSSION.

Dr. KNIGHT remarked that this subject was a very obscure one. He had once seen a patient who had fallen down stairs and struck on the top of the head, who afterward noticed an alteration in his voice, and, on subsequent examination, the only symptom or sign resulting from the accident was paralysis of one abductor. It was one of the most striking cases in favor of independent nerve-supply of the abductors. At any rate, it showed that there was some lesion which affected the abductor without affecting the adductor. It was not very likely that there had been any injury of the abductor muscle itself.

THE TREATMENT OF FRACTURE OF THE PATELLA.*

By J. H. HOBART BURGE, M. D., BROOKLYN,

VISITING SURGEON TO THE LONG ISLAND COLLEGE HOSPITAL, CONSULTING
SURGEON TO ST. JOHN'S HOSPITAL.

WHAT are the indications in the treatment of fracture of the patella? Obviously, as in other fractures where displacement has occurred, to put the fragments as nearly as possible into their normal relation to each other, and keep them there until union, in this case generally ligamentous, has taken place and has become strong enough to resist all ordinary influences which would at an earlier period be likely, in whole or in part, to break it up.

A marked feature of the method which I employ is the weight and pulley, and the superiority of this over all other modes of retention can, in my opinion, hardly be over-estimated. All other appliances for the retention of the fragments in this fracture, excepting, of course, Malgaigne's hooks, relax speedily, and have to be very frequently renewed or readjusted, and, in my experience, this is a constant temptation to make them uncomfortably tight. This is also true of the different methods of tying together with separate strings, at the side of the patella, the bands which press directly upon the bone. This objection is obviated when these separate ties are elastic, but these ties only help still more to hide from view the part which requires frequent inspection in order that the surgeon may know and feel that all is going well.

If I am not mistaken, I was the first to use the *axis in peritrochio* in the treatment of this injury. You will find my apparatus described and illustrated in the "Medical Record" for April 15, 1868, and in Hamilton on "Fractures and Dislocations," 4th edition. In these days, when

almost all of our good things are traced back to the first and second centuries, we may well be a little diffident in claiming originality for anything, but, if the fathers did use this method, it was forgotten, and I revived it sixteen years ago. The apparatus, which I show to-night for the first time in any society, I have used in both hospital and private practice with great satisfaction. A very short description will suffice, since a glance at the instrument itself, or at the accompanying woodcut, will make all plain.

The padded straight board upon which the limb rests is five or six inches wide throughout its length, except that the upper end is somewhat broader, for the comfort of the patient. It is divided and hinged opposite the knee, to provide for slight passive motion, of which I shall speak further on. A movable foot-piece is attached. This straight board is hinged at its upper end to another board of about equal length, and wide enough at its middle third for the insertion of screws supporting little brass wheels, around which the cords are passed to the weights at the foot of the bed. The splints proper are of sole-leather—one about a foot long, five or six inches broad at its upper end, narrowed toward the knee, and made concave at its lower end to fit the upper border of the patella; the other splint about three inches and a half both in breadth and in length, cut out at its upper margin so as to fit the lower border of the bone. These splints of sole-leather should be soaked a few minutes in cold water, till they are quite pliable—hot water makes them too soft, and lengthens the time required for drying. Pad one side of each splint with cotton-wool, and cover neatly with ordinary unbleached muslin. Bind both splints to the limb as nearly as possible in the position which they are intended to occupy, with a roller bandage. In a few hours they will be thoroughly molded to the limb and as firm as a board. The roller can then be removed. A small strong cord, for the attachment of the weights, should now be sewed firmly just above the concave margin of each splint and passed through the pulleys, as shown in the apparatus before you.

The splints are now so firm and fit so accurately that bandages are unnecessary. They require only to be tied in place, the bands passing not directly about the limb, but under the board upon which the limb rests. It may be well to pin these bands to the splints to prevent their slipping. The weights may vary from one to three or four pounds.

When I first introduced this apparatus I made for it the following claims, which have been fully justified by subsequent experience :

* Read before the Medical Society of the County of Kings, July 15, 1884.

1. It leaves the injured bone so exposed to the surgeon's observation that he need have no anxiety in reference to *tilting, side-slipping, or retracting* of the fragments.

2. It grasps so firmly and yet so tenderly the quadriceps extensor, together with the upper fragment of the bone, that it enables us to approximate the broken surfaces more completely than I have ever been able to do without violence.

3. It is comfortable to the patient.

4. It is inexpensive, simple in all its parts, easily extemporized, and easily applied.

The entire cost is about three dollars. Any ordinary carpenter can finish the wood-work in two hours. If any member of the profession desires to put this appliance to the test in his own practice, I will loan it to him, either for use or as a pattern to make one by.

I can now make one more claim—viz., that, while the fragments are thoroughly held in place, such a degree of passive motion can be made from time to time as will greatly lessen the stiffness of the joint which so often annoys our patient for months after he is allowed to go at large.

Provision is made for elevating the foot to the extent of 30°, though the utility of this practice has, I think, been reasonably questioned.

My friend, Dr. James L. Little, of New York, uses plaster of Paris, making a clear distinction between a plaster *bandage* and a plaster *splint*. He applies a firm splint of plaster to the posterior aspect of the limb, and also plaster splints of coaptation to the broken bone, and covering all with a roller. In his experienced hands, no doubt good results are obtained; but, in the very nature of things, these coaptation splints must relax, especially if the patient gets about on crutches. If in any given case there are special reasons for getting the patient up, Dr. Little's posterior splint is excellent, but, if he is to remain in bed, it seems to me to confine the knee unnecessarily, and to favor the false ankylosis to which reference has been made. The strictures of Dr. F. H. Hamilton upon plaster of Paris as a dressing in the treatment of fractures are strong, and, I think, in the main well founded. Yet it must not be forgotten that great improvements have been made in all the details of its application. I have been surprised at the skill displayed by some surgeons in the use of this material. Nevertheless, I think it can not be used with safety by those who have had little surgical experience.

Dr. Little emphasizes an important point in writing of his appliance by the use of the following italics: "*This dressing differs essentially from all others in that the fragments are adjusted by the hands of the surgeon, and the setting of the plaster keeps them in the exact position in which they are held.*" It is fair to say that the doctor had not seen my apparatus, for by its use the surgeon can at any moment separate the splints of coaptation and adjust the fragments, or, what is better still, assure himself that no adjusting is necessary. He has then only to allow the splints to be drawn gently into place again, as they are by the weights, which never tire and never relax.

A CASE OF CÆSAREAN OPERATION.*

By GEORGE T. HARRISON, M.D.,
ASSISTANT SURGEON TO THE WOMAN'S HOSPITAL.

THE specimen which I here exhibit is a uterus removed after death from a woman who had a contracted pelvis, in consequence of which I found it necessary to perform the Cæsarean section. The history of the case briefly is as follows:

The patient was thirty-one years of age, married, a primipara. During early childhood she suffered from rickets. She was unable to walk until the fourth year. After she recovered from this disease her health became excellent. When I saw her for the first time, on the 6th of February, she was suffering from a slight bronchitis. Otherwise she enjoyed good health. During the whole period of pregnancy she had suffered comparatively few annoyances, had had a good appetite, and had slept well. On the 22d of March the patient sent for me, being alarmed because there were no signs of commencing labor, according to her count she having reached full term. An examination *per vaginam* showed that the head was above the superior strait, and I then recognized the fact that there was narrowing, and supposed it to be a case of flattened pelvis. At that time I did not know that she had had rickets.

Reckoning from the last menstruation, I told her that labor was likely to come on about the 25th of March. It was not, however, until the night of the 4th of April that labor pains began. On the morning of the 5th I found the pains recurring at intervals of twenty minutes, but no apparent effect had been produced on the cervix. April 5th, 6th, and 7th the first stage dragged along slowly. Hypodermic injections of morphine were administered several times, to give the patient an opportunity to procure rest. On the afternoon of the 7th I thought it was time to interfere, and sent for Dr. A. R. Robinson, who appointed 9 p. m. as the hour at which he could meet me. I asked Dr. R. C. M. Page to be present at the same time. The patient was put under ether, and an attempt was made, after manual dilatation of the os (the os being dilatable), to apply the forceps. This was soon abandoned, as it was found impossible to bring the head down by its use. I then tried version, but, after reaching the child's legs *in utero*, my arm was grasped so tightly by the sphincter vagina that my hand did not retain sufficient power to seize the foot, and I had to give place to Dr. Robinson, who succeeded in seizing a foot and bringing it down. After many futile efforts at version, we decided that it was impossible to extract the child in this way.

The only alternative open to us now was laparo-hysterotomy. At my request the husband went for Dr. Gillette, who came at once and gave me the benefit of his skill and experience. Dr. Page giving ether, with the assistance of Dr. Robinson and Dr. Gillette, at about 1 p. m. I proceeded to the performance of this operation. The child proved to be a very large one. Its weight subsequently was found to be eleven pounds and three quarters. The edges of the wound in the uterus were brought together by a continuous suture of silk. The patient reacted well from the operation. The next day her condition was favorable. The third day, however, peritonitis showed itself, and, on the evening of April 10th, at 7.30, she expired.

Autopsy, April 11th, by Dr. B. A. Lindsey.—Extensive peritonitis. Union along the whole line of the abdominal wound. The wound in the uterus also united. Accurate measurement

* Read before the New York Obstetrical Society, April 15, 1884.

showed the conjugate diameter to have a length of two inches and three quarters. The transverse diameter was four inches and a quarter. It was, therefore, a rachitic flattened, generally contracted pelvis.

A WOUND OF THE ABDOMEN. INVOLVING THE UMBILICUS. FOLLOWED BY HÆMATURIA.

By L. J. DAILEY, M.D.,

REDFORD, N. Y.

On the evening of the 26th of March I was called to see W. S., a boy of thirteen years of age, who, a few hours previously, had received a penetrating wound of the abdomen by sliding from a hay-mow on to a pitch-fork that rested against it. One of the tines of the fork entered the skin at a point an inch and a half below and one inch to the left of the umbilicus, passing upward and slightly inward through the superficial fascia and the aponeurosis of the external oblique until it reached the umbilicus, as ascertained by probing. There was very little external hæmorrhage, from the fact that it did not pass entirely through the walls of the abdomen, and therefore did not reach the peritonæum or bowels.

I was led to give a very favorable prognosis, and, after prescribing an opiate to quiet the little existing pain that he complained of and making a local application to the wound, I left, with a promise to see him again next day. On arriving there about noon the following day, I was surprised to learn that during the night the patient had passed a large quantity of bloody urine, and, as it had been several hours since he had urinated and as there appeared to be some distension of the bladder, as ascertained by percussion, I asked him if he did not want to make water, to which he replied in the affirmative, and, getting out of bed with but very little assistance, he passed nearly a pint of bloody urine without any difficulty and without producing the least pain, except a slight feeling of uneasiness at the wound, due to the contraction of the abdominal muscles which occurs during micturition. The patient continued to pass bloody urine until the fifth day after receiving the injury, when it entirely disappeared, the patient going about on the sixth nearly as well as ever. There was no sign of traumatic peritonitis, either circumscribed or general, there was but a slight elevation of temperature at any time, and the pulse was but little accelerated.

The point that remains to be cleared up and to be answered is, how the blood reached the bladder and was voided with the urine from a wound that was entirely above and in a direction away from that organ. There was no injury of the abdominal viscera, as the probe was arrested on reaching the umbilicus, showing that the penetration did not extend beyond that point. The ureters could not have been injured, from the direction taken by the fork, and there was no injury of the urethra, vas deferens, or prostate, that would account for the hæmaturia; and the only way that I can possibly account for it is in the presumptive existence of a pervious urachus, even at the age of the patient—namely, thirteen years. "The summit or apex of the bladder," says Gray, "is rounded and directed forward and upward; it is connected to the umbilicus by a fibro-muscular cord, the urachus, and also by means of two rounded fibrous cords, the obliterated portions of the hypogastric arteries, which are placed one on each side of the urachus. The urachus is the obliterated remains of a tubular canal

which exists in the embryo and connects the cavity of the bladder with a membranous sac, placed external to the abdomen opposite the umbilicus, called the allantois. In the infant, at birth, it is occasionally pervious, so that the urine escapes at the umbilicus." Here we find that Gray only states that it is *occasionally* found pervious at birth. Therefore I ask if it would be unreasonable to suppose that, in this particular case, it remained pervious at thirteen, and that it was the means of conveying the blood from the wound to the bladder. In conclusion, I will add that there was no hæmorrhagic extravasation or discoloration of any part. I have never seen or heard of such a case before, and, in looking up the literature of such injuries, I fail to find any record of any. Therefore I am forced to the conclusion that it is rather unique.

Book Notices.

Diseases of the Heart and Thoracic Aorta. By BYRON BRAMWELL, M.D., F. R. C. P. E., Lecturer on the Principles and Practice of Medicine, and on Practical Medicine and Medical Diagnosis, in the Extra-academical School of Medicine, Edinburgh, etc. With 317 Illustrations. Edinburgh: Young J. Pentland, 1884. Pp. xvi+783.
The Same. New York: D. Appleton & Co., 1884. [Price, cloth, \$8.]

ONE of the first prerequisites to writing a good book is an intimate knowledge of the subject which one is to write about. Huxley has forcibly remarked, in his lectures on biology, that the important practical facts in that comprehensive science, or rather group of sciences, can not be obtained by the mere reading of books, and the conclusion is obvious that there is need of extensive observation and investigation on the part of one who would instruct us in so important a department of the science of life as is occupied by diseases of the heart. The author's fifteen years of service in a renowned school, as teacher and investigator, have certainly furnished him with opportunities for gaining the necessary information, and we have the result of his labors in the handsome volume which is before us. The construction of the work is rational and simple. After the general considerations concerning cardiac anatomy and pathology, the diseases of the covering of the heart are first studied, then those of its lining, next those of its muscular and nervous structure. These chapters are followed by a brief consideration of the diseases of the aorta. In style the author has adhered closely, and at first one might perhaps be inclined to say too closely, to the style of the lecture-room, but it will be seen by a note in the preface that the work is essentially the text of his lectures during the lecture season of 1883-'84.

In the pages which are devoted to the preliminary considerations of his subject several points are noteworthy. We may mention his analysis of the cause of heart-motion, which is exhaustive, clear, and satisfactory; also his acceptance of the conclusion of Martin and Sedgwick that the coronary arteries receive their blood supply during systole, which is contrary to previously received notions. He also accepts the doctrine that the influence of the cardiac ganglia is not indispensable to the rhythmic action of the heart. In this portion of his work, being largely physiological, we find him depending upon physiologists, and especially upon Gaskell, for his propositions.

The chapter upon the general pathology of the heart is a

very satisfactory one. This portion of the subject is, in any one's hands, far less intricate than several of those which follow, but all men are not equally happy with our author in explaining intelligibly even simple propositions. The use of a homely phrase is sometimes very expressive and convincing, and he has taken advantage of this fact in several instances; for example, the term *back-wash* is frequently substituted as an equivalent for *regurgitation*.

In the succeeding chapter we are brought into deeper water. Clinical investigation of cases, case-taking, inspection, and palpation are plain enough, and are explained with sufficient clearness; there is some obscurity in connection with percussion; and auscultation and sphygmography are intricate enough, especially the former. The explanatory diagrams are but partially successful, because they only demonstrate, and that imperfectly, the length of the given heart-sounds. The source of the difficulty, and we are referring now particularly to auscultation, lies in the intrinsic obscurity of the subject itself. What words can depict to a dull ear, and perhaps a dull mind, the differentiation between two synchronous heart-sounds—that is to say, the two synchronous sounds which are emitted with each diastole and systole of the right and left hearts? Our author would probably reply, Such persons should not auscultate. But they will continue to do it, or rather to attempt it, in spite of faulty teaching and dull perceptions, and fortunate will that man be who can devise a system of models and pictures whereby this obscure subject may be made clear. Certain portions of this chapter would be credited with prolixity by any but devoted and advanced students of cardiac pathology, notably the discussion concerning the nature and significance of the basic murmur which is heard in the second left interspace in the earlier stages of anemia (pp. 189–207). The author's devotedness to his subject undoubtedly justified (at least to himself) this protracted attention, on the ground of thoroughness. The same might be said of his remarks concerning those useful instruments of precision, the sphygmograph and the cardiograph (the latter being described at length in the appendix).

Diseases of the pericardium are fairly and plainly discussed. In regard to suppurative pericarditis, the author favors treatment by incision, an operation which is formidable enough, and which, according to his statement, has been done successfully only twice. Adherent pericardium is described as a separate disease. We fail to see either the advantage or the propriety of such a classification, since, by the author's own description, there is no combination of symptoms differing from those which are found in the corresponding condition in chronic pericarditis.

In the description of acute endocarditis, in the chapter upon diseases of the endocardium, we see a marked contrast to the terse, vigorous, and clear description which may be found in Reynolds's "System of Medicine" (Vol. III), which is quoted by the author. He expresses with positiveness his belief that mitral lesions in connection with endocarditis may be, and often are, recovered from. While his position upon this point may be a very good one, he does not sustain it by good logic. Thus he says (p. 377): "If, then, choreic endocarditis with vegetations can be recovered from, why can not rheumatic endocarditis with vegetations be recovered from?" Admitting that his previous reasoning upon the identity of rheumatic and choreic endocarditis is correct, and adopting his own conclusion, we find him saying finally: "In fact, in many cases [*italics are ours*] the choreic endocarditis is undoubtedly rheumatic." From the foregoing the defect in his argument is manifest.

The only allusion in this work to the influence of micro-organisms upon heart lesions is to be found in the section upon ulcerative endocarditis. The results of the investigations of Osler and Klebs upon this subject are quoted with a *quasi* ap-

proval, but it is plain to be seen that our author has not contracted the "bacterial craze," as some skeptic has recently designated it.

Concerning the remaining diseases which are discussed, comment at this time is unnecessary. Several of them are too obscure, as the author admits, to be recognized during life, and are therefore mainly of interest to the pathologist. We could wish that more attention had been given to the subject of cardiac therapeutics, and less, as has already been hinted, to theoretical considerations. We desire to refer now to a feature which is one of the most excellent which this book contains—namely, the three hundred and seventeen illustrations which are mentioned in the title. Those which represent the anatomy, physiology, and topography of the heart are unpretentious in character, whether diagrammatic or detailed, but, in the main, are entirely clear and satisfactory. Of a more ambitious character are the full-page lithographs, illustrating in natural size the various lesions which are described. There is no work upon this subject, so far as we are aware, which is comparable with this one in that respect. We would suggest, however, for a future edition, either the stronger shading of the diseased portions, as represented in the picture, or the suitable coloring of the same, though at the expense of the present artistic effect, which is quite admirable.

The impression which this book has given us, and which will be created, we believe, in the professional world, is a very gratifying one. It is not without faults, and what book is? As a careful, conscientious, and thorough work upon cardiac disease, we wish it all the success which it is certain to get.

The International Encyclopædia of Surgery. A Systematic Treatise on the Theory and Practice of Surgery, by Authors of Various Nations. Edited by JOHN ABBOT, JR., M. D., Professor of Clinical Surgery in the University of Pennsylvania. Illustrated with Chromo-lithographs and Woodcuts. In Six Volumes. Vol. IV. New York: William Wood & Co., 1884. Pp. xxiii–987.

The fourth volume of this important work is devoted chiefly to diseases of the bones and joints, a part being given up, however, to the question of tumors. The first chapter is by Dr. John H. Packard, and relates to injuries of bones. All but one page of the two hundred and sixty composing the article are devoted to fractures, the other injuries being contusions and incised and punctured wounds, which are dismissed in a few words. Gunshot wounds have been previously discussed. The question of fracture is well treated, the discussion being neither too diffuse nor too much given up to different forms of splints. The author has aimed at general principles while describing each fracture in detail, and by so doing has given a very readable and instructive article.

Chapter II is by Mr. Barwell, of London, and treats of diseases of the joints. It includes morbus coxarius, the different varieties of synovitis, loose bodies, the gouty and rheumatic affections, ankylosis, the neuroses, and tumors, and is one of the most exhaustive in the work.

The article on excisions and resections is by the editor; and a special chapter on excision of the knee is contributed by Dr. Fenwick, of Montreal, who has had such good results as regards subsequent shortening. The two together cover the whole ground, the operations upon each joint and each particular bone being described in full, with many valuable tables of results.

The article on tumors is by Mr. Henry Trentham Butlin, of St. Bartholomew's Hospital, London. It covers rather more than two hundred pages, and is profusely illustrated, clear and plain, and excellent for reference.

The late Dr. Lidell wrote on the somewhat general subject of injuries of the back, including those of the spine, its membranes, and the spinal cord, while Mr. Treves, of the London Hospital, deals with malformations and diseases of the spine, and closes the volume.

We are glad to see that as the work approaches completion it loses nothing of the characteristics which made it so favorably received at first, and we await with interest the two remaining volumes, which will complete a very valuable collection of surgical literature.

Transactions of the American Surgical Association. Volume the First. Edited by J. EWING MEARS, M. D., Recorder of the Association. Philadelphia: P. Blakiston, Son & Co., 1883. Pp. xxxi-568.

In reading over this, the first volume issued by the American Surgical Association, we are pleased at its scientific character. It contains the papers read from September, 1880, to June, 1883, and the matter contained in it compares favorably with the report of any other society in America of which we have any knowledge. Judging from the character of these papers, the association means to do good work, and has fairly begun.

Taking the papers in detail, the first is by Dr. S. W. Gross, on the Influence of Operations upon the Prolongation of Life and Permanent Recovery in Carcinoma of the Breast, in which he reaches the conclusions, among others, that local reproductions do not militate against a permanent recovery, provided they are freely excised as soon as they appear; that lymphatic involvement does not forbid operation, since infected glands were removed in more than one third of the examples of final cure; that the subjects are, almost without exception, safe from local and general reproduction if three years have elapsed since the last operation; and that all carcinomata of the breast, if there are no evidences of metastatic tumors, and if thorough removal is practicable, should be dealt with as early as possible by amputating the entire mamma with its integuments, dissecting off the subjacent fascia, and opening the axilla with a view to its exploration and the removal of any glands which were not palpable prior to interference.

Other articles by the same author are upon the Condition of the Cicatrices after Complete Expiration of the Breast for Carcinoma, and a Case of Nephrectomy for Medullary Carcinoma and Partial Chole-cystectomy for Calculus, in the same subject.

The second paper is the report of a case of supposed spontaneous aneurysm of the posterior tibial artery, by Dr. R. A. Kinloch, of Charleston, with a table of twenty-two similar cases.

There are two papers by Dr. Packard, of Philadelphia, the first a report of some Difficult Cases of (Esophagotomy, and the second on Ligation of the Primitive Iliac Artery for the Relief of Secondary Hæmorrhage after Amputation at the Hip Joint.

Dr. James A. Cabell, Dr. W. T. Briggs, and Dr. B. A. Watson each contribute papers on the question of Antiseptic Treatment, which is discussed pro and con with considerable vigor.

Dr. Gunn discusses the Treatment of Fractures of the Skull, and formulates his convictions on the subject as follows: In all recent fractures with depression, whether simple or compound, even though entirely without symptoms of compression, if there is reason to believe that the internal table is depressed, and if there are no symptoms of marked concussion or collapse, elevation of the depressed portion should be promptly effected. In chronic cases, as soon as positive, even though slight, symptoms of cerebral irritation present themselves, a disc of the cranial walls intended to include the irritating point should be removed with the trephine.

Dr. R. J. Levis has an article on the Treatment of Fracture of the Patella with the Object of producing Bony Union, and

Dr. Moore, of Rochester, gives a paper on Section of the Femur for the Relief of Bony Ankylosis of the Hip Joint in Bad Position, one on Fracture of the Femur, and one on Luxation of the Ulna in connection with Colles's Fracture.

There is a very exhaustive and elaborate paper by Dr. Senn also on Fractures of the Neck of the Femur, with special reference to Bony Union after Intra-capsular Fracture, which is one of the best in the book; and there are other noteworthy papers on Excision of the Tarsus, by Dr. P. S. Conner; on Foreign Bodies in the Air-passages—a Study of One Thousand Cases to determine the propriety of Bronchotomy; on Dislocations of the Astragalus, by Dr. Basil Norris, U. S. A.; and one on the Removal of Meckel's Ganglion for the Relief of Trifacial Neuralgia; besides several other shorter contributions, all of which are good.

The book is exceedingly well edited and well printed, and is, on the whole, a very attractive and valuable addition to surgical literature.

A System of Oral Surgery: Being a Treatise on the Diseases and Surgery of the Mouth, Jaws, Face, Teeth, and Associate Parts. By JAMES E. GARRETTSON, M. D., D. D. S., Dean of the Philadelphia Dental College, etc. Illustrated with numerous steel plates and woodcuts. Fourth edition, thoroughly revised, with additions. Philadelphia: J. B. Lippincott & Co., 1884. Pp. 1,037.

THE last edition of this work was reviewed in this journal only two years ago, and its merits were pointed out. The present volume is larger than the last, contains many new illustrations and several chapters of new matter, and is better in every way. From its title it might be supposed to be a work for the dentist rather than the surgeon, but every disease pertaining to the mouth or the parts adjacent to the mouth comes in for notice. There are chapters on inflammation, on anæsthesia, on nerve-stretching for neuralgia, on tumors of the antrum, on salivary fistula, on the tonsils, on the pharynx, on the nose, and on the skin diseases affecting the face. In other words, as well as being a work on dentistry, it is a work on the general surgery of all the parts in any way associated with the mouth. In the present edition the author has aimed at completeness and conciseness; he has handled a wider range of subjects than before, and handled them very thoroughly. There is a great deal of matter in the work which can not be found in general surgical text-books, and it is now, we suppose, generally used as a text-book in the dental colleges.

A Manual of Practical Hygiene. By EDMUND A. PARKES, M. D., F. R. S., etc. Edited by F. S. B. DECHAUMONT, M. D., F. R. S., etc. With an Appendix, giving the American Practice in Matters relating to Hygiene, prepared by and under the supervision of FREDERICK N. OWEN, Civil and Sanitary Engineer. Two volumes in one. New York: William Wood & Co., 1884. Pp. xv-556.

PRACTICAL hygiene, in the sense in which it is taken in this book, is a subject with which the large majority of physicians are, alas! quite unfamiliar. One cause of this is the splitting up of the science of medicine into its many specialties; another is that very many physicians have neither the time nor the inclination to give it the attention which it requires. This fact must not be forgotten, however, that in many communities in our country the physician is the authority on all matters which pertain to sanitation. Certainly for such there is a responsibility which can not well be shirked, and we commend this standard work to them and to all who are interested in the subject. The foregoing applies more particularly to that portion of the work which refers to State medicine, the value of which

is becoming more apparent with the development of our country. Such questions as the influence of climate and soil, atmospheric phenomena, the water-supply, sewerage, etc., are of interest to no one if not to the physician. The value of a book like this, which is comprehensive but not diffuse, can therefore be appreciated by a busy man who will require it for reference. The subject of foods, which is, of course, dealt with from its physiological standpoint, introduces many questions of physiology and organic chemistry, which are eminently practical and are treated of with satisfactory clearness. That portion of the work which is devoted to military hygiene in the British army in different parts of the world, interesting and valuable as it is, would seem to us either superfluous or requiring condensation in an American edition. A series of chapters on military hygiene, appropriate to the conditions of our own army, might well be substituted for it, if, indeed, this subject were not better considered in a work by itself. The appendix contains a series of short essays on American State medicine, which seem all too meager when compared with the work which has been compassed in the chapters that precede them.

A Practical Treatise on Surgical Diagnosis, designed as a Manual for Practitioners and Students in Medicine. By AMBROSE L. RANNEY, M. D., Professor of Practical Anatomy in the New York Post-Graduate Medical School, etc. Third edition, thoroughly revised, enlarged, and profusely illustrated. New York: William Wood & Co., 1884. Pp. xx-608.

DR. RANNEY is to be congratulated on the appearance of the third edition of this well-known work in a more complete form and profusely illustrated. New matter has been added relating to diseases of the brain and spinal cord, and what was previously published has been revised as suggestions and corrections have occurred to the author.

As it now stands it is an exceedingly valuable reference-book for the student, and has been found to be such by several of the medical colleges. The contents are well indexed, and whatever points one may desire to look up can be found clearly stated at a glance.

Illustrations of the Influence of the Mind upon the Body in Health and Disease, designed to elucidate the Action of the Imagination. By DANIEL HACK TUKE, M. D., F. R. C. P., LL. D., etc. Second American from the second English edition. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. xviii-33 to 482, inclusive.

WITHIN the pages of this ample work Dr. Tuke has collected a large number of cases which serve to exhibit in a more or less striking manner the intimate relationship between mental phenomena and bodily function. As its title denotes, the volume is devoted to the illustration of certain psycho-physical principles which the author believes to be clearly discernible in the light of recent physiological research. He has used great diligence in collecting and classifying cases, and no pains have been spared to ascertain the absolute authenticity of every one of them.

Not only has the influence of the mind upon the body in health, as shown by various disorders of sensation and motion of purely psychical origin, received attention, but the same principle has been traced out in the domain of disease. Very interesting in this connection are the cases adduced as corroborative evidence of the great value of the psychological element as an adjunct in the treatment of an extensive class of diseases.

The work is divided into four parts. Part first treats of the intellect, part second of the emotions, part third of volition, and

part fourth of the influence of the mind upon the body in the cure of disease. The first chapter is devoted to the consideration of general psychological and physiological principles. The second, third, fourth, and fifth treat of the influence of the intellect upon sensation, upon the voluntary and involuntary muscles, and upon the organic functions. In the seventh, eighth, ninth, tenth, and eleventh chapters the influence of the emotions is considered. The thirteenth and fourteenth chapters are devoted to the discussion of the influence of the will upon sensation, the voluntary and involuntary muscles, and the organic functions; while in the fifteenth, sixteenth, and seventeenth chapters the influence of the mind upon the body in the cure of disease is abundantly illustrated by a mass of cases, many of which, it is true, make strong demands upon the reader's credulity.

It is impossible to peruse these interesting chapters without being convinced of the author's perfect sincerity, impartiality, and thorough mental grasp. The subject is by no means a simple one, and the danger of confounding cause and effect are frequently by no means inconsiderable. Nevertheless, Dr. Tuke has exhibited the requisite amount of scientific address on all occasions, and the more intricate the phenomena the more firmly has he adhered to a physiological and rational method of interpretation. Nebular theorizing and transcendental hypotheses find no place here. Guided by an enlightened deduction, the author has reclaimed for science a most interesting domain in psychology previously abandoned to charlatans and empirics. This book, well conceived and well written, must commend itself to every thoughtful understanding.

BOOKS AND PAMPHLETS RECEIVED.

Practical Manual of Diseases of Women and Uterine Therapeutics. For Students and Practitioners. By H. Macnaughton Jones, M. D., M. C. H., F. R. C. S. I. & E., Examiner in Obstetrics, Royal University of Ireland, etc. New York: D. Appleton & Co., 1884. Pp. xxiii-410.

Text-Book of Medical Jurisprudence and Toxicology. By John J. Reese, M. D., Professor of Medical Jurisprudence and Toxicology in the University of Pennsylvania, etc. Philadelphia: P. Blakiston, Son & Co., 1884. Pp. xii-9 to 606, inclusive.

Lehrbuch der Physiologie für akademische Vorlesungen und zum Selbststudium. Begründet von Rud. Wagner, fortgeführt von Otto Funke, neu herausgegeben von Dr. A. Gruenhagen, Professor der medicin. Physik an der Universität zu Königsberg i. Pr. Siebente, neu bearbeitete Auflage, mit etwa Zweihundertundfünfzig in den Text eingedruckten Holzschnitten. Zweite Lieferung. Hamburg und Leipzig: Leopold Voss, 1884. Pp. 161 to 320, inclusive.

Diphtheria, Croup, etc. Or, the Membranous Diseases: their Nature, History, Causes, and Treatment; with a Review of the Prevailing Theories and Practice of the Medical Profession; also, a Delineation of the New Chloral Hydrate Method of Treating the same; its Superior Success and its Title to be considered a Specific. By C. B. Galentin, M. D. New York: J. H. Vail & Co., 1884. Pp. viii-174.

The Formation of Poisons by Micro-organisms. A Biological Study of the Germ Theory of Disease. By G. V. Black, M. D., D. D. S. Philadelphia: P. Blakiston, Son & Co., 1884. Pp. viii-11 to 178, inclusive. [Price, \$1.50.]

Contributions of Physicians to English and American Literature. By Robert C. Kennen, M. D., South Carrollton, Ky. [Report from the "Medical and Surgical Reporter."]

Fifth Annual Report of the State Board of Health of Illinois.

NEW YORK, SATURDAY, SEPTEMBER 6, 1884.

THE INTERNATIONAL COLLECTIVE INVESTIGATION OF
DISEASE.

EVERY school-boy is familiar with the statement that at a certain stage in his career Alexander the Great sighed for more worlds to conquer; but there is this much to be said in Alexander's behalf, that he had accomplished something toward the conquest of the only world known to him before he heaved this historic sigh. Can as much be said for the promoters of the project termed the collective investigation of disease? We can not avoid this question in connection with the proposal to press the machinery of the International Medical Congress into the service of what seems just now to be the pet scheme of the British Medical Association.

Considerable time has elapsed since this dream of science "made easy"—of a grand republic of scientific investigators—took fast hold upon the minds of a great number of our British friends; it has met with a feeble attempt at imitation on our own territory, as witness the fiasco in the Medical Society of the County of New York last winter; and it appears to have made itself profoundly felt in Germany. And what has it accomplished? Has it settled anything? Has it even investigated anything in a way to put previous investigators to the blush? If it has done any of these things, we have failed to perceive it. What can it reasonably be expected to achieve so long as it distributes cards inscribed "Have you observed any case or cases in which pulmonary phthisis appeared to be communicated from one to another? Please answer Yes or No"? And yet this was the example of its workings which Sir William Gull thought proper to put forward in his address at the Copenhagen session of the International Medical Congress, wherein, with masterly eloquence, he asked that body to take up the prosecution of the scheme. At best, the answers to such a question, coming from a great body of men of diverse views, would constitute but a catalogue of raw impressions; and we can conceive of few things more hazardous to the prospect of our ever being able to build up an exact science of medicine than to generalize from such data. We might as well expect to clear up the hoop-snake myth by ballot, the polls being thrown open to everybody who had ever chanced to roam the fields.

We have watched this collective investigation movement with a good deal of interest, but hitherto we have refrained from any general comment on it. We have felt from the first that, while much was to be hoped for from it, nothing was to be expected, for it has seemed to us that the world was not yet ready for the successful working of such a method of accumulating data. When the facts to be observed are of a nature to call for exquisite discrimination on the part of the observers,

and when, as in medicine, concerted observation calls for a thorough understanding by each observer of the others' capacity and mental methods, it is rarely that even two investigators are to be found who can work together to advantage; that a great number of such men should be found, seems utterly out of the question. To multiply the number of observers is to depreciate the general quality of the work. We feel, therefore, that the system of the collective investigation of disease might better be confined within a comparatively narrow field until experience has shown that it is to some extent adequate to its purpose.

THE BOSTON CITY HOSPITAL.

It is now twenty years or more since this institution first opened its doors to the sick poor, and the measure of good which it has accomplished in that short period by affording shelter and medical treatment to persons deserving of its ministrations, great as it undoubtedly is, is not out of proportion to its contributions to the common stock of medical knowledge. It is true that many years have passed without a continuation of the series of portly volumes—similar in character to the annual reports issued by the great hospitals of London—of which the first was published soon after the opening of the institution. Our remembrance of that volume is that the work of preparing it fell upon a very small proportion of the members of the hospital staff, and, for the credit of the profession, we prefer to suppose that the lack of succeeding volumes of late years has been more owing to a natural disinclination on the part of those few gentlemen to bear the burden longer than to any failure of the work to meet with the practical recognition it so well deserved. But it is not alone by such publications that a hospital can make itself felt in the profession. By the excellence of its practice, and by the amount and the character of the clinical teaching it maintains, it takes a standing concerning which there is no ambiguity. In both these particulars, we have reason to feel convinced, the Boston City Hospital has made a most creditable showing, as, indeed, could scarcely have failed to be the case, considering the *personnel* of its staff.

Like our New York hospitals, the institution in question finds itself constantly exposed to imposition by persons who either are improper subjects for treatment in a general hospital or, being proper subjects in other respects, belong to a class for which the benefits of a free hospital were never intended. In the Twentieth Report of the Trustees, for the year 1883-'84, a manly attempt is made to open the eyes of the people of Boston to the fact that a free hospital should be free only to persons who, by misfortune or poverty, may require relief during temporary sickness. Quoting from a committee's report, made to the City Council in 1857, the trustees say: "We would not have this a hospital for the degraded victims of vice and intemperance, or as the home for the hopeless pauper; but we would have it regarded as an asylum for the industrious and honest mechanic and laborer who, by sudden injury or disease, is temporarily prevented from laboring for his own or his family's

support, and who, by proper care and medical advice, may have his suffering alleviated and be sooner restored to his health and his family, and be enabled to resume his labors." It strikes us that this very correctly expresses the proper design of a free general hospital. We learn by the report of the superintendent and resident physician that, of those who applied for admission during the year, 1,872 were not admitted: 75 for want of accommodation, 235 who needed only outpatient treatment, 124 non-residents, 48 who "applied but changed their minds," 8 who could not be found when calls were made at the addresses they gave, 148 who were the subjects of chronic and incurable disease (besides 99 with phthisis), 168 victims of delirium tremens and other forms of alcoholism, 155 with venereal disease, 33 pregnant women, 69 malingers, 15 subjects of mental disease, 10 who were "under age," 121 who were referred to other appropriate institutions, and 64 who are classed as "miscellaneous."

Valuable statistical tables are appended, prepared by the medical staff, showing the character of the injuries and diseases for which relief was sought, both in the wards and in the outpatient department, the various operations performed, and the terminations of the cases. These tables show the marks of very careful preparation, and in regard to the statistics of the hospital, as in every other respect, we must congratulate the medical staff.

THE "WORLD'S" MEDICAL DEPARTMENT.

THE "World's" senseless and offensive account of a hysterectomy performed at the New York Hospital, to which we lately adverted, turns out, according to what we consider trustworthy information, to have been furnished to that paper by a medical student whom circumstances enabled to be present where his company was not desired. Unless we misapprehend the temper of the hospital authorities, the individual will not hereafter find things so favorable to his purposes at that particular institution; but that may matter little to him, for there are those who, in a dearth of facts, know how to take refuge in invention. As for the "World," we did think better of it than to suppose that it would continue to admit into its columns the productions of a person of whom, apart from what had been shown to be his utter disregard of propriety, it could only be said that he was a fit candidate for the plucking process, if he were ever to "come up."

But we see now that we gave the "World" too much credit, and it is apparent that it has determined on a medical department as one of its regular features, for on Thursday last it returned to its vomit. This time it is "Professor Sabine, of the College of Physicians and Surgeons, the leading rhinoplastic or skin-grafting surgeon in the world," that it takes under its wing; and it proceeds to give an account of how he recently made "a real nose, one that could snore and be wiped with a handkerchief, . . . warranted or money returned." This exploit is said to have been performed at Bellevue Hospital, and the name of the patient is given. Evidently, after these fine touches of humor on the part of its contributor, the "World" must think

itself *très ha-ha*, to use an expression said to be of the approved Parisian style of slang.

Both Dr. Sabine and Dr. Bull, for it was the latter whose operation furnished the inspiration for our medical student's first journalistic flight, are gentlemen who are not easily disconcerted, and we therefore do not expect to hear of their having waylaid their persecutor; moreover, there is this redeeming feature about the matter, that the very ridiculousness of the statements made by him will go far to rob them of their sting. In the interest of decency, however, the question becomes still more pressing, whether, as we suggested on a former occasion, something can not be done to protect our hospital surgeons against newspaper reports that those who do not know them may be uncharitable enough to look upon as having been inspired by them.

MINOR PARAGRAPHS.

FROM "THE BUGS" TO BLACK VOMIT.

ON Tuesday night of last week a policeman found a man lying helpless on a truck in Cherry Street, and this is how the officer stated his diagnosis: "Well, I'll be blowed if I don't think you've got the bugs." An ambulance was sent for, and the man was then said to have typhoid fever. He was finally admitted into the New York Hospital, not many hours before his death, and there the conclusion was reached promptly that he was suffering from yellow fever—a diagnosis that the post-mortem examination abundantly corroborated.

Who the man was, or whence he found his way to the truck, we have not yet been told, and some uneasiness has been felt as the result of the uncertainties wrapped up in this absence of facts. The idea seems to be pretty generally entertained, however, that the victim was a sailor, although this is little more than pure conjecture, founded on the fact that his feet were soiled with tar; and the circumstance that his general make-up failed to stamp him as a seaman outright has led to the supposition that he was a stowaway who had been made to work his way to this port on a short voyage. There is nothing to indicate that he found his way into the streets directly from any vessel in port, and hence the horrible suspicion is entertained that the keeper of some sailors' boarding-house, more acute to perceive the nature of the poor fellow's sickness than the policeman and the ambulance surgeon proved to be, inhumanly thrust him out to die in the street.

Whatever truth there may be in any of these surmises, this grim fact stares us in the face—that yellow fever has eluded our quarantine system, perhaps, as one of the newspapers has suggested, by a vessel having landed stealthily in the East River after coming through Hell Gate. On the whole, the affair is not calculated to increase public confidence either in our sanitary officials or in our detective force.

THE AMERICAN DERMATOLOGICAL ASSOCIATION.

ON several occasions we have called attention to the excellent character of the work done in dermatology in this country, including the proceedings of this association. The annual meeting, held last week, a report of which will be found elsewhere in this issue of the journal, was quite up to the mark, whether we regard the character of the papers read, the tone of the discussions, the proportion of attention given to each of the two branches—dermatology proper and syphilidology—to the study of which the association is devoted, or the attendance of gentlemen practicing these specialties in various parts of the country.

In some of its features, indeed, the meeting seems to us to have been in advance of those held in preceding years—the discussions were held well to the point, so that, so far as we can judge from the report, there was none of the rambling and even rancorous talk that has sometimes figured. Nor do we perceive any signs of the bootless contest having been revived between the diathetic and the local systems of etiology. The association is to be congratulated not only upon the high character of the proceedings at this meeting, but also, and perhaps to a greater degree, upon the continued spread of the interest taken in dermatology, as shown by the number of gentlemen newly elected to membership.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 2, 1884:

DISEASES.	Week ending Aug. 26.		Week ending Sept. 2.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid Fever.....	26	14	32	15
Scarlet Fever.....	32	6	25	4
Cerebro-spinal meningitis ..	2	2	4	4
Measles.....	47	11	37	11
Diphtheria.....	22	11	25	15
Yellow Fever.....	0	0	1	1

The Cholera in the South of Europe still maintains a threatening attitude, especially in Italy, where some ten or twelve considerable towns, notably Naples, are suffering, notwithstanding the extraordinary measures that were resorted to to keep the disease out of the country. There are reports also of cases in Spain. A press dispatch received from London on Thursday contained a report of a case having occurred in that city, coupled with the statement that the sanitary officials doubted its genuineness.

The New York Academy of Medicine was to have received a legacy of \$5,000 under the will of the late Dr. John G. Adams, but it is now stated that, by a recent codicil, the bequest to the Academy is limited to the greater part of the books forming Dr. Adams's library. A member of the profession, who is not a member of the Academy, authorizes us to say that he will give the sum of \$500 toward the amount that would have been received by the Academy but for the codicil, provided the remainder of the \$5,000 is raised by private subscription.

The Inventor of Chlorodyne, Dr. J. Collis Browne, formerly of the British army, is reported to have died lately.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 23, 1884, to August 31, 1884:*

HEAD, JOHN F., Colonel, and Surgeon. Granted leave of absence for four months. S. O. 201, A. G. O., August 27, 1884.

WOODHULL, A. A., Major and Surgeon. Detailed as member of Medical Examining Board at United States Military Academy, West Point, N. Y., vice Captain R. H. White, relieved. Upon adjournment of the board to return to his proper station. S. O. 201, C. S., A. G. O.

LIPPINCOTT, HENRY. Promoted Major and Surgeon, to rank from August 17, 1884, vice Woodward, deceased.

BARTHOLO, J. H., Captain and Assistant Surgeon. Relieved from duty in Department of the Columbia, and to report in person to commanding general, Department of Texas, for assignment to duty. S. O. 199, A. G. O., August 25, 1884.

FINLEY, J. A., Captain and Assistant Surgeon. The leave of

absence granted him in S. O. 91, C. S., Department of Texas, extended two months. S. O. 198, A. G. O., August 23, 1884.

TAYLOR, M. E., Captain and Assistant Surgeon. Granted leave of absence for four months, to take effect on arrival of a medical officer at David's Island, N. Y., to replace him. S. O. 200, A. G. O., August 26, 1884.

GIBSON, R. J., First Lieutenant and Assistant Surgeon. Relieved from duty in Department of the Missouri and ordered to Department of California for duty. S. O. 202, A. G. O., August 28, 1884.

DIETZ, WILLIAM D., First Lieutenant and Assistant Surgeon. Relieved from duty at the Military Academy, West Point, N. Y., and ordered to the Department of the Missouri for duty. S. O. 202, A. G. O., August 28, 1884.

McCRAW, WALTER D. Appointed Assistant Surgeon with rank of First Lieutenant, to date from August 20, 1884.

Society Meetings for the Coming Week:

MONDAY, September 8th: American Association for the Advancement of Science (Philadelphia—fourth day); New York Ophthalmological Society (private); New York Medico-Historical Society (private); New York Academy of Sciences (Section in Chemistry and Technology).

TUESDAY, September 9th: American Association for the Advancement of Science (fifth day); Medical Society of Virginia (Rawley Springs—first day); Medical Societies of the Counties of Chemung, Rensselaer, and Ulster, N. Y.; Essex, N. J., Medical Association; Trenton, N. J., Medical Association (private).

WEDNESDAY, September 10th: American Association for the Advancement of Science (sixth day); Medical Society of Virginia (second day); New York Pathological Society: American Microscopical Society of the City of New York; New York Medico-Legal Society; Medical Societies of the Counties of Cayuga and Montgomery, N. Y., and Middlesex, N. J.

THURSDAY, September 11th: Medical Society of Virginia (third day); Harlem Medical Association.

FRIDAY, September 12th: Medical Society of Virginia (fourth day); Yorkville Medical Association (private); Medical Society of the Town of Saugerties, N. Y.

OBITUARY NOTES.

Dr. Robert J. Heinmuller died on Saturday last at his residence, No. 222 East Thirty-second Street, at the age of twenty-nine. He was graduated from the Medical Department of the University of the City of New York in 1875. In 1881 he became connected with the Health Department, and occupied the position of Assistant Sanitary Inspector in the Bureau of Contagious Diseases. He was a member of the Medical Society of the County of New York and of the Physicians' Mutual Aid Association. His death is said to have been due to apoplexy.

Proceedings of Societies

AMERICAN DERMATOLOGICAL ASSOCIATION.

Eighth Annual Meeting, held at Highland Falls, N. Y., Wednesday, Thursday, and Friday, August 27, 28, and 29, 1884.

Wednesday's Proceedings.

The President's Introductory Remarks.—After the report of the Council and the transaction of some routine business, the President, Dr. R. W. TAYLOR, of New York, made a few introductory remarks, in which he spoke of the high posi-

tion occupied by the association in the dermatological world, and extended a hearty welcome to the members. He then declared the meeting open for scientific work.

A Case of Xanthoma Multiplex was the title of the first paper, by Dr. W. A. HARDWAY, of St. Louis. The patient was a man, aged forty-four, who was well until the age of thirty, with the exception of hyperidrosis of the feet, from which he had long suffered. For some years he had worked eight hours daily before a hot fire, which caused excessive general sweating. This ceased after a while, however, giving place to intense burning and itching. Two years later he noticed that he was turning yellow, and his health began to run down. When first seen, some years later, his right side was of a bronzed hue, his left side yellow. The skin disease on account of which he presented himself had appeared four years before. He said that he had suffered from intolerable itching for twelve years. He usually had a ravenous appetite, but felt weak and was often dizzy. He was found to have pulmonary emphysema, and said that he often had attacks of asthma. His temperature was normal; the urine was acid, of the specific gravity of 1.016, and contained a trace of sugar, but no albumin or casts. The liver was much enlarged downward and laterally, thickened, and nodulated. The skin was bronzed and almost black in some places. The conjunctiva was also stained. Marks of furious, long-continued scratching were evident over the whole skin, and the hair was almost destroyed in many places. On the eyelids, lips, and chin were numerous well marked patches of xanthoma. Around the elbows, on the wrists, the backs of the hands, and the feet, also on the buttocks, thighs, and legs, were a very large number of xanthomatous tubercles, varying from a pin-head to a hickory-nut in size, a few being umbilicated, and some, on the face, perforated by hairs. The palms of the hands also presented many small tubercles and bands of yellow infiltrated tissue. One of the joints of the second finger of the left hand was much enlarged, and all the malleoli were enlarged (by bone) to twice their natural size. A number of tumors could be recognized in the subcutaneous fat-tissue of various portions of the body, and a distinct bony node could be seen over the front of the head of each tibia.

The greater portion of the trunk was free from tubercles, but on the right side, covering the site of the eleventh and twelfth and a part of the ninth and tenth ribs, were many groups, composed of a large number of yellow xanthomatous tubercles having the exact distribution of the vesicles of herpes zoster, stopping at the median line before and behind. In some parts of this extensive patch of disease the tubercles had become confluent. These had existed for a long time, and the patient gave an uncertain history of pain in the part before they appeared. The glans penis and the scrotum were involved, and there were small patches of yellow-discolored tissue in the mucous membrane of the inner aspect of the cheeks and of that of the soft palate, and also in those of the larynx and trachea. The general symptoms of which the patient complained were due to the emphysema and to a great distension of the abdomen. The tumors did not annoy him much, although they were also the seat of the itching which involved the whole skin.

The most striking points in the case, in the author's opinion, were the facts that the bronzing of the skin antedated the appearance of the xanthoma lesions by a number of years, and that the eruption was perfectly symmetrical, except on the trunk; the involvement of the mucous membranes of the air-passages and of internal organs was also very interesting. The distribution of the tubercles seated on the side of the trunk would seem to prove that the nerves might have some influence in the development of the lesions of xanthoma. He would also call particular attention to the presence of tubercles in the ar-

olar tissue and in the tendons, and to the probable implication of the bones, as shown by the enlargement of the tibiae and the malleoli. The fact that some of the growths had undergone involution was also striking. His study of this and other cases, and of the literature of the subject, led him to venture the suggestion that xanthoma was a diathetic affection, and that the connection of the disease with derangement of the liver was entirely secondary. He believed that when jaundice occurred it did so in consequence of a deposition of tubercles in the liver. He was also inclined to believe that in persons with what he would call the "xanthomatous diathesis" prolonged irritation or motion at certain points would cause a development of tubercles at those points, as over the articulations, on the eyelids, etc. Finally, he thought it possible that the lesions on the chest-wall might be due to an abortive attack of herpes zoster.

Dr. S. SHERWELL, of Brooklyn, said that he had never succeeded in tracing a connection between the disease under consideration and hepatic affections. He had seen quite a number of cases of the disease, and the patients were all healthy people otherwise.

Dr. J. C. WHITE, of Boston, said that it was extremely rare to find jaundice associated with xanthoma; he himself had noticed the connection only once in many cases that he had seen. He had seen only one case of xanthoma multiplex. He did not believe that there was anything of a diathetic nature at the bottom of xanthoma, but he had seen several cases in one and the same family.

Dr. L. A. DUHRING, of Philadelphia, called attention to the fact that the pruritus began with the jaundice and not with the xanthoma. He was inclined to believe in a connection between the tumors met with in this disease and those occurring in some forms of the affection described as urticaria pigmentosa, under which latter term, he thought, two different classes of affection were often described.

The PRESIDENT agreed with the other speakers in denying any connection between xanthoma and a diathesis, as he had found the disease in the healthy as often as in those suffering from gout, rheumatism, or other diathetic conditions. He did not believe that involution of the lesions, if it ever took place, would occur on the face, where the spots, he believed, were always permanent.

Dr. HARDWAY said that he had only the patient's statement to prove that involution of some of the lesions had taken place. He regretted that no one had thrown any light on the bone lesions of the case, which, to him, were involved in great obscurity as regarded their relations to the disease.

A Clinical Study of Lupus Erythematosus as it affects the Hand.—At the evening session Dr. J. NEVINS HYDE, of Chicago, read a paper with this title. He described in detail the symptoms of the disease as exhibited by four patients under his observation—three females and one male. In each the discoid variety of the disease was shown upon one hand, and of the four patients only one had facial lesions, which came out some years after the disease was fully developed on the hand. In several of the cases the fingers were involved, and in one the palm was not affected. The paper terminated by a presentation of other cases, recorded in literature, of the same form of the affection. The prominent features in each case were tabulated. From this comparison it appeared that the average age of the patients was somewhat over twenty years, and that almost two thirds of them were women, thus confirming the observations made by Kaposi in 1882. The cases in which the hands were affected had all been recorded by either American or English observers.

Dr. WHITE stated that he had seen three or four cases of lupus erythematosus in which the hands alone were affected.

He had also seen cases of the disseminated form of the disease, in which the hands were free. In none of them had he been able to recognize any evidences of a depraved condition of the system. He thought that cases of the disease in which the palms were implicated were not extremely rare, but that the affection was often overlooked, being regarded as some other disease.

Dr. SHERWELL had never seen the disease in question on the palms, but had seen it on the backs of the hands.

The PRESIDENT had seen two cases of the affection as described in the paper—one in a man, the other in a woman. Both were in good health and seemed free from diathetic taint.

Dr. HYDE stated that his main object in writing the paper had been to point out the ease with which the affection could be recognized, and to add to the literature of the subject.

A Suggestion for the Treatment of Acne and Acne Rosacea in the Male Subject was the title of the next paper, read by Dr. SHERWELL. He said that too little attention had been paid to disturbances of the genital tract as causes of these diseases, and gave credit to Piffard and Hyde for having recognized their importance in this regard. He then spoke of the occurrence of chronic congestion and hyperæsthesia of the male urethra in some cases, and recommended for its relief the use of cold-steel urethral sounds. He concluded by detailing two cases which were thus cured.

Dr. A. R. ROBINSON, of New York, thought the suggestion a sensible one, and that benefit would result from heeding it in some cases.

Dr. G. H. FOX, of New York, spoke of the liability of physicians to ascribe results to a certain plan of treatment when the improvement might have been due to a change in regimen on the part of the patient unknown to the physician. He also thought well of Dr. Sherwell's suggestion.

A Case of Unilateral Chromidrosis (?).—Under this title, Dr. WHITE read a paper which contained a report of the case of a workman in a sugar refinery whose shirt had been stained a bright-yellow color for several months. After wearing it a few days, the left side all the way down seemed as if stained by saffron. There was apparently no excessive perspiration of that side of the body, nor were the garments stained elsewhere. An analysis of the material absorbed by the shirt showed that it was of an oily character, readily extracted by ether, and yielding peculiar absorption bands when examined with the spectroscope. Its nature was not more definitely determined. It was also uncertain whether it was secreted by the sudoriparous or by the sebaceous glands. The color was not due to the presence of bacteria, which had been found in some of the few cases of yellow sweat reported. The affection was immediately controlled by local treatment, and had not recurred four months later.

Dr. DUHRING thought the description read gave an accurate notion of the disease, and he saw no reason to doubt that it was a case of genuine chromidrosis. He had recently seen a case of red sweat, in a young woman, where it occurred in spots over the body.

Dr. FOX had never seen any cases of genuine chromidrosis. He spoke of one which he had thought was genuine, but which was found to be due to the red color from a blanket having been rubbed off on the face during the night.

Dr. HARDAWAY and Dr. HYDE had seen cases almost identical with that mentioned by the last speaker.

Dr. WHITE said that the query-mark after the title of the paper was placed there because he was uncertain as to whether the yellow matter came from the sweat or from the sebaceous glands.

Cases of Arsenical Dermatitis.—Dr. WHITE read another

paper, in which he gave brief notes of cases of supposed arsenical dermatitis, in connection with the report of a train of uncommon cutaneous manifestations in a mother and her newborn child, the birth having taken place in a chamber the walls of which were covered with arsenical pigments. The object of the paper was to raise the question, how far the apparent "pityriasis maculata et circinata" in the mother was dependent upon the presence of arsenical compounds in the atmosphere of the lying-in chamber, for it was an affection concerning the ætiological relations of which nothing was known. In the infant the symptoms were of an eczematous type, with unusual manifestations of intertrigo.

Dr. HYDE remarked that the number of artificial dermatoses was multiplying rapidly, and thought that the question as to a possible artificial origin should always be raised in doubtful cases.

Dr. SHERWELL said that the recital of the cases had made him think that certain obscure cases of bullous eruption now under his observation might be cases of this nature.

Dr. WHITE thought it more likely, from the description given, that they were cases of an unusual form of poisoning from the bites of mosquitoes, of which he had seen many.

Thursday's Proceedings.

Dermatitis Herpetiformis and its Relations to Impetigo Herpetiformis was the title of a paper by Dr. DUHRING, which was practically a synopsis of one read at the last meeting of the American Medical Association, and discussed in its final portion the relations of the disease treated of to the affection long ago described by Hebra under the name impetigo herpetiformis, which usually occurred in pregnant or puerperal women, and generally resulted fatally. The paper aimed to establish the identity of the two affections, and also that of a number of diseases closely resembling the cases of Hebra, which had been described under a variety of names, such as pemphigus pruriginosus, herpes chronicus, herpes gestationis, etc.

Dr. FOX thought great credit was due the author for taking this comprehensive view of many varying forms of disease, the proper place of which in dermatological nomenclature had so puzzled observers. He now felt confident that they all belonged in the class which Dr. Duhring had established. He then briefly reported a case recently under his care, which he had called chronic erythema multiforme pigmentosum. The eruption consisted of blebs all over the body and extremities, with here and there ridges of a papular form of lesions, attended with swelling of the arms and legs. There were many cicatrices over the body, left by the blebs; and the skin, which before the onset of the disease was said to have been unusually white, was deeply pigmented. The patient had an outbreak of blebs at each menstrual period. She had improved greatly under the use of arsenic, but he did not anticipate complete recovery. It seemed to him that the name impetigo multiformis would better define the disease in this case, however, than that suggested by Dr. Duhring.

Dr. H. G. PIFFARD, of New York, said that the disease which the author of the paper had so ably described was rare, and its manifestations were not sharply defined. He felt sure that many cases hitherto described under various names might with perfect propriety be comprised in the comprehensive view of the matter taken by Dr. Duhring. He himself did not believe that the affection was in any manner allied to herpes, taking its most typical form, zoster, as a standard of comparison. Morphologically, it could not be classed with that affection, the lesions of the disease described in the paper being too multiform. He had recently seen a case of the affection, which he described at length.

Dr. WHITE was convinced that the more such cases were studied the greater would be the difficulty experienced in classifying them. He was inclined to think that the term "multiform dermatitis" would apply to them better than the others which had been suggested. He was not quite ready to admit that the writer of the paper had proved the existence of an absolute connection of the cases he had brought forward with those of Hebra, however. Still, as he had never seen a case such as Hebra had depicted, he would regard the question as still undecided. He saw no reason to accept the view advanced by the author of the paper that the disease was usually of a neurotic origin. He thought that by the general practitioner the disease was apt to be mistaken for eczema.

Dr. HARDAWAY thought that a certain number of cases, in which the lesions were papules, vesicles, and pustules, could properly bear the title "herpetiform." He believed there was a neurotic basis to many of them.

Dr. ROBINSON spoke of three cases of the disease he had seen, and showed a colored drawing illustrating one of them. The eruption was polymorphous, looking in some places like ringworm, in others like pemphigus, and in others almost like keloid. He had recognized a well-marked neurotic element in the case, had put the patient, a boy of ten years, on the use of nine drops of Fowler's solution three times daily, and great improvement had followed.

Dr. SHERWELL believed that Hebra's cases had been of a septic origin, and that they resembled closely many cases which he had seen in military hospitals infected with hospital gangrene.

Dr. DUHRING stated that his paper was based upon the study of sixteen or seventeen cases of the affection which had been under his observation for a number of years. He could not regard the objection which had been advanced against the qualifying adjective herpetiform as valid, since in many of the cases there was from the first a distinctly herpetic character. He reiterated his opinion that the difference between his cases and those of Hebra was simply one of degree.

Friday's Proceedings.

A Case of late Cutaneous Syphilis (Acneiform Syphiloderm of the Nose) illustrating the occasional Necessity of Large Doses of Potassium Iodide.—A paper with this title, by Dr. H. W. STELWAGON, of Philadelphia, was read by the secretary, in the absence of the author.

The evidences of syphilis in the case were obscure, and the diagnosis was for a time uncertain. Only after the patient had for some time taken drachm-doses of the iodide of potassium three times daily did the disease begin to yield.

A Case of Vitiligo involving the Whole Surface was the title of another paper by Dr. STELWAGON, also read by the secretary. It described accurately the progress of the disease and the appearance presented by the patient after its full development.

A Case of General Idiopathic Atrophy of the Skin.—Dr. HARDAWAY read a paper with this title, and showed photographs illustrating it. The patient was a blind man, twenty-three years old, who had a blind sister who, he said, had the same skin disease. His face presented a rosaceous aspect, the skin being thickened and reddened. There were scars around the mouth, and the lips presented a strumous appearance. The trunk had a checkered shining aspect, due to many pigmented spots of various sizes and atrophic patches, over which the skin was tense and glistening, and could be picked up with difficulty. No dilated vessels were visible. The skin and muscles of the hand were atrophied, and the sides of the fingers were adherent to each other over half their extent. Examination of the eyes

showed xerosis of the conjunctiva, adhesion of the lids to the globes, and corneal opacities.

Dr. DUHRING said that, beyond atrophy, there were no special features which distinguished the disease under consideration, neither dilated vessels nor pigmentation being essential features. We met with cases of all grades of severity, from those having no tendency to degeneration to those developing carcinoma or sarcoma.

The PRESIDENT said that, in his opinion, the condition of the skin in Dr. Hardaway's case was not like that met with in angioma pigmentosum et atrophicum, this patient presenting simply an ill-nourished, senile-like condition of his integument. The process in him had not been active enough to lead to neoplastic formations.

Dr. WHITE was unable to agree with Dr. Duhring as to the affinity which he believed to exist between the different varieties of atrophic processes in the skin, which varied widely from one another. In one class we met with loss of pigment and a deposition of epithelium, without changes in the corium; in another hypertrophy of the corium was a marked feature; in a third variety new growths were developed. He did not think the case reported could be associated with these last.

Miliaria and Sudamina.—Dr. ROBINSON then read a paper on this subject. He first quoted the views held by different authors as to the true nature of a dew-drop-like eruption described under a number of names, such as miliaria alba, m. rubra, sudamina, eczema solare, lichen tropicus, etc., and showed that they conflicted greatly. His object in preparing the paper had been to attempt to clearly define the true nature of the affections under consideration, the conclusions he had reached being based upon original microscopical studies. He concluded that miliaria alba and m. rubra were forms of eczema, due to heat, irritating clothing, acrid sweat, etc. He therefore thought that the term should be dropped.

The disease known as sudamina he had found to be not an inflammatory affection, but a disturbance of the sweat-glands, the result of a hyperidrosis. The paper was illustrated by many drawings.

Dr. HARDAWAY objected to the use of the term *eczematous* as applied to the affection under consideration, which was a true dermatitis, while eczema was a distinct disease.

Dr. HYDE was inclined to fully adopt the views advocated in the paper. He thought that miliaria and sudamina were due solely to accidents occurring in the course of an eczema.

Dr. WHITE thought that any attempt to lessen the confusion in dermatological nomenclature should be welcomed. He regarded the position taken by the author of the paper as the only philosophical one. He himself recognized no such diseases as miliaria alba and rubra as distinct affections, but regarded them merely as forms of eczema. The question was, after all, one of definition only.

Dr. DUHRING, while giving full credit to the author of the paper for the valuable nature of his work, was still not prepared to look upon miliaria alba as a form of eczema. The clinical histories of the two diseases varied widely, the former being acute and self-limited, the other tending to a chronic course.

A Peculiar Ringed Affection of the Glans and Prepuce was the title of the next paper, by the PRESIDENT, Dr. R. W. TAYLOR. He described three cases of the affection, seen during the past ten years. The patients were all from forty to forty-five years of age, and all free from syphilis. Marked neurotic disturbances preceded and attended the outbreak in all the cases, and one patient had had an attack of orchio-epididymitis and recurring attacks of balanoposthitis, and in another a chancre had been roughly cauterized, which led to long-continued swelling and inflammatory disturbances. In all the cases the

disease appeared in the form of rings covered with thin, firmly adherent scales, and seated upon an apparently normal mucous membrane. These lesions remained for a long time stationary, neither spreading nor disappearing. Disagreeable sensations in and around the affected parts were complained of. He had recognized the existence of a marked neurotic element in all the cases. The disease proved obstinate, but finally yielded to increasing doses of arsenic persistently used. The author was loath to regard the disease as *sui generis*, but, in attempting a diagnosis, he had carefully eliminated syphilis, tinea circinata, and psoriasis.

Dr. DUHRING had seen several cases of the disease, he thought. In his cases there were no subjective symptoms, however, but the gross appearances and the course and evolution of the lesions had irresistibly suggested lupus erythematosus. He was inclined to believe that the president's cases were also instances of that affection.

Dr. WHITE had had one case under observation for some time. He had made no positive diagnosis, and the patient had not recovered.

Dr. HARDWAY described a similar case in a man who had had psoriasis. The lesion on the glans, however, was totally unlike psoriasis.

Dr. WIGGLESWORTH, of Boston, cited the case of a man whom he had cured of leukoplakia buccalis, and who afterward developed a lesion on the penis like those described by the president. It finally disappeared under the use of pure carbolic acid.

The PRESIDENT was confident that his cases were not instances of lupus erythematosus, as they had not developed from papules, there were no recurrent attacks of hyperæmia, the patches were not indurated, and there was no cicatrization.

The following-named gentlemen were elected officers for the ensuing year: Dr. W. A. HARDWAY, of St. Louis, president; Dr. J. C. GRAHAM, of Toronto, and Dr. A. VAN HARMINGEN, of Philadelphia, vice-presidents; Dr. W. T. ALEXANDER, of New York, secretary; and Dr. GEORGE H. ROSE, of Baltimore, treasurer.

Mr. JONATHAN HUTCHINSON, of London, England, was elected an honorary member; and the following-named gentlemen were elected active members: Dr. GEORGE H. TILDEN, of Boston; Dr. A. R. MORISON, of Baltimore; Dr. F. O. CURTIS, of Albany; and Dr. L. N. DENSLOW, of Minneapolis.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Meeting of July 15, 1884.

The President, Dr. JOHN A. MCCORKLE, in the chair.

The Treatment of Fracture of the Patella was the subject of a paper read by Dr. J. H. HOBART BURGE. [See page 259.]

Dr. HOPKINS said he would like to call attention to the peculiarities of some cases of fracture of the patella. He supposed he was somewhat heretical in the belief that we made too much of fractures of the patella. In the larger proportion of cases, so far as the use of the limb was concerned, it made little difference whether the union was ligamentous or bony, so called. In the vast majority of cases the union was undoubtedly ligamentous. We saw the fragments sometimes separated to a great distance without causing any very great lameness or inconvenience. He thought that often the bone could be fractured without having the ligament broken, as the latter was distributed principally on either side of the patella, scarcely any fibers being found on the inner or posterior surface, and only a few on the anterior surface of the bone. In such a fracture as this it made little difference whether the union was ligamentous or not, whether the

bones were brought together closely or not, or whether there was some ligament intervening. He remembered a case which was remarkable in that there was a fracture of both patellæ. The injury was produced in going down stairs. In that case two fingers could be laid between the fragments. The person was not at all lame subsequently. There ought to be a distinction made between fracture of the ligament and bone and fracture of the bone, which he believed could exist alone. If the ligament was ruptured, there ought to be an apparatus to bring the parts together, or there would be lameness. In the case to which he had referred the fragments were three inches and a half apart, and the woman walked without apparent lameness. He had had a note from her, which, with the permission of the society, he would read, in which she described her injury, and which he thought might be of interest. There was a triangular depression between the lower end of the femur and the head of the tibia, into which he could lay all the fingers of his hand without their rising above the surface.

He then read the letter, as follows:

"My knee-pan was broken September 3, 1877. When I broke it I was standing on the stair and my knee just gave way under me. I was not able to move; I felt powerless, and did not know what was the matter until the doctor examined it. I was laid up from September 3d to January 7th. The pan of my knee has never been removed, half being above and half below my knee. I have no power to lift my leg off the ground [except so far as is required in walking], but that does not interfere with my walking, for I do not walk lame, and the only inconvenience I suffer is going up and down stairs, as I can only take one step at a time. Whenever I am tired or weak it bends in the wrong direction—so much so sometimes that I fall down. My knee was well enough for me to travel with a splint on, and I came home to Canada on the 7th of January. After a while I thought it was well enough to walk without a splint, so I took it off, and during the winter had seven heavy falls on my knee, which [I forced] it [the fragments] farther and farther apart, and left it as it now is."

He cited this case to show how much a person could do without really having any union of the bone at all. Of course, if the patient had some apparatus to prevent the knee from going backward while walking down stairs, she could walk as well as anybody. He had advised her to get such an appliance. This was an extreme case, and he was surprised at the way she walked with really no patella to help her. He thought the case might be of interest in connection with Dr. Burge's paper.

Recent Advances in the Treatment of Wounds was the subject of remarks by Dr. LEWIS S. PILCHER. [See page 254.]

G. R. BUTLER, M. D., *Secretary pro tem.*

NEW YORK OBSTETRICAL SOCIETY.

A STATED meeting was held April 15, 1884, WILLIAM M. POLK, M. D., president, in the chair.

Carcinoma of the Breast.—Dr. M. A. Pallen presented a specimen of carcinoma of the breast removed on the 27th of March by a double-flap operation, the incision extending about ten inches, in nearly a horizontal direction, across the breast. The patient was also seen by Dr. Thomas. There was considerable hæmorrhage, a number of vessels had to be tied, and it was considered advisable to pass a deep silver suture and bring the lips of the inner angle of the wound firmly together. Forty minutes after the operation hæmorrhage again occurred, which was controlled with ligatures and deep wire sutures. As many as eight bleeding vessels were tied and five or six silver-wire sutures inserted deep in closing the wound again. A drainage-tube was inserted. Twenty-four hours later the temperature

began to rise and the wound was constantly bathed with a solution of carbolic acid in water and with Listerine. Whenever the wound was flooded, by closing the distal end of the tube, the temperature immediately fell. Symptoms of septicæmia continued for nine days, and then the patient began to recover. The highest temperature was 104.2° F.

This was the only instance in which Dr. Pallen had practiced Dr. Thoma's method by horizontal incisions. For cases in which the tumor was non-malignant, and the breast not flabby or fatty, he thought it probably as good a method as that which he, and most other surgeons, had generally practiced—namely, by a long vertical incision. The latter method gave better opportunity for drainage, and was preferable, he thought, to the former, especially in cases in which the breasts were large.

Dr. T. G. THOMAS said he could recognize, as Dr. Pallen had mentioned, the great advantage of ease of drainage by the up-and-down incision, but it seemed to him that the chief advantage of the horizontal incision had been overlooked. It was a matter of primary importance in removing the breast to open the way to the axillary space, that enlarged glands might be sought for and, if found, be removed. Surgeons were generally agreed that, if the operation was to be done at all, the axillary region should be thoroughly explored and all traces of malignant disease be extirpated. It was true that after the up-and-down incision the external flap could be lifted and the axillary space be investigated, but, in case hæmorrhage should be considerable, it would be almost impossible to arrest it without then making a horizontal incision, to find the vessels and tie them. Only the day before the meeting he had removed a large mammary tumor, with the assistance of Dr. Chambers, in which some of the axillary glands had attained to the size of marbles. It was necessary to carry the incision well back to the posterior border of the axilla, and dissect out the enlarged glands with great care, to avoid wounding plexuses of nerves and vessels which were plainly visible. Considerable hæmorrhage occurred, and he had to cut quite deep to control it. It was necessary, he thought, in every case of carcinoma of the breast to explore the axillary region by an incision, for inability to feel the enlarged glands through the integument did not prove their absence. He asked Dr. Pallen if he did not think the horizontal incision was preferable where it was necessary to explore the axillary region.

Dr. Pallen thought that where it was necessary to remove the axillary glands he should make the horizontal incision. If that were not necessary, he should prefer the longitudinal incision, as being more rapid and easier to make, and as affording better drainage.

Supra-vaginal Myomotomy.—Dr. T. A. EMMET presented a uterus which he had removed a week before from a woman, forty-eight years of age, who had menstruated very freely for many years. About two years ago she had first noticed the development of an abdominal tumor, supposed to be a uterine fibroid. She was under the care of Dr. Wilson, of Baltimore, who felt positive that the tumor was a fibroid. After having done all that could be done in the way of treatment, he sent the patient to her home in Virginia. But about six months ago the abdomen began to increase rapidly in size, and, when she arrived in New York, the abdominal measurement was forty-four inches. There was apparently a large fibrous tumor, and it was thought there might also be a cyst, but the solidity of feel was such that it was difficult to make a positive diagnosis. The patient's condition was too low to enable her to return home, and it was decided to do an operation. On opening the abdomen, the large tumor was found to be a dermoid cyst with very thick contents, containing teeth and a flat bone, but no

hair. After emptying the dermoid cyst the uterus was reached, and was found to contain a fibro-cyst. In accordance with the advice of Dr. Hunter and Dr. Lee, who were present, but against his own judgment, he determined to remove the uterus. First the dermoid cyst was removed, and afterward the other (the left) ovary, which was enlarged and cystic, was removed, together with the tube, according to Tait's method. Bleeding points were tied, and he then proceeded to dissect the bladder away from the uterus, and, having extended the dissection low down upon the neck, passed a double ligature around the cervix and the pedicle of the tumor; but only a small amount of the peritonæum, at the bottom of Douglas's *cul-de-sac*, was included in the ligature. Injury to the bladder was avoided by leaving it partially distended with urine while it was being separated from the uterus. The portion of peritonæum and bladder which had been dissected away from the tumor was then turned over the stump like a hood, and fastened at the bottom of the posterior *cul-de-sac* by fine silk sutures. Much to his surprise, the patient had done well since the operation, and he thought she would entirely recover. A peculiarity in the case was the fact that before and after the operation, until within two or three days, the respirations had been as many as thirty to the minute. The highest temperature reached was 102.2° F. The patient for some days past had been somewhat hysterical. Dr. Emmet believed that if myomotomy was to have a future, it would have to be done by covering the stump with the peritonæum and dropping it into the peritoneal cavity. In the cases in which he had operated before, the clamp was applied to the stump and fastened at the abdominal wound, but all the patients had died from one cause or another. It should be said, however, that Mr. Thornton had obtained success only in cases in which the clamp had been used. He thought it rare for a dermoid cyst to begin to develop so late in life, and then for the first time attract attention. He would not have operated upon this patient had it not been that she was losing an excessive amount of blood, and it was a curious fact, learned after removal of the tumor, that the hæmorrhage was in no way connected with the fibroid tumor, but was due to a polypus within the uterine canal which could not be reached or appreciated during life.

Dr. THOMAS said the desirability of covering the stump had been recognized for some time by Schröder and other European operators, and had been practiced more or less, but not according to the method described by Dr. Emmet. He should think that in some cases this method would prove very valuable indeed. That adopted by operators abroad, and which he had practiced in a number of cases, consisted in overlapping the stump with the remaining portions of the anterior and posterior surfaces of the uterus, as one would close the gap left after amputation of the breast. He thought the finding of the polypus as the cause of the hæmorrhage was an exceedingly interesting and important fact. He believed that as a rule, to which there were few exceptions, subperitoneal fibrous tumors very rarely caused hæmorrhage. Interstitial fibrous tumors rarely caused hæmorrhage unless they produced fungoid degeneration of the endometrium or were accompanied by a polypus. But interstitial fibroids would induce fungoid growths, and they were also often accompanied by small polypi, and Dr. Emmet's case was an illustration of that fact. He fully agreed with Dr. Emmet, however, that one could not have reached the polypus to remove it by the vagina. With regard to the development of dermoid cysts in patients advancing in age, he had operated in a number of cases in which the cyst had not become much distended with serum or pus until after the thirty-fifth or fortieth year. Of course the tumor had been present during the whole of life, but had been of small size.

The PRESIDENT inquired if it might not be possible to re-

move the polypoid growth in some other way than by the usual method, and thus avoid the necessity for so severe an operation as hysterectomy. Might not the os be reached by a lateral abdominal incision, as in laparo-elytrotomy?

Dr. THOMAS thought it would be difficult to reach the os in that manner, and especially to perform dilatation. It would seem that the less severe operation of the two would be to remove the uterus. He had removed the uterus from seventeen patients, nine of whom had recovered and the remainder had died. A large number had been treated by the clamp, and they had done remarkably well. A smaller number had been treated by simply returning the pedicle, and they had done badly. Most of the operations had been supra-vaginal; that is to say, he had removed the uterus as low down as possible. In a few instances he had been able to remove the entire uterus, and in several had even made a pedicle of the vagina. Dr. Hunter had also had a success recently with the clamp, and Dr. Dawson had had a patient recover in whose case the clamp was applied near the middle of the uterus.

The PRESIDENT remarked that thirteen out of fourteen patients treated by Dr. Keith by the extra-peritoneal method had recovered.

Cæsarean Section.—Dr. G. T. HARRISON reported a case. (See page 260.)

The PRESIDENT asked why the operation had been postponed until the 7th, labor having begun on the morning of the 5th; also what the source of septic infection was.

Dr. HARRISON replied that the os had not dilated, and there were no indications for earlier interference. He further stated that the cause of the peritonitis was septic infection, which doubtless took place from necessary manipulation of the uterus during the operation.

The PRESIDENT had inquired particularly with regard to the source of septic infection, because upon this he thought depended largely the test as to whether the Porro operation was to take the place of the old classical Cæsarean section. In this case and in the one reported by Dr. Garrigues, union of the uterine wound had taken place throughout its entire length, and there was no chance for the escape of the lochia into the peritoneal cavity a few hours after the operation. It appeared that Dr. Garrigues's patient had died on account of her reduced state before the operation was performed; Dr. Harrison's from peritonitis as a primary result of the operation, and not from an escape of septic poison through the uterine wound after the sutures had been applied. If infection had taken place later, through the wound in the uterus, it would militate against the Cæsarean operation.

Dr. THOMAS replied to a question by Dr. Harrison that he did not know what bearing the presence of the leg in the vagina would have upon laparo-elytrotomy. In the cases in which he had done the operation he had found it of advantage to have the vaginal canal unobstructed.

In two cases in which the PRESIDENT had performed Cæsarean section in the interest of the child, the mother being moribund, he had found the operation very much facilitated by making a large abdominal wound, turning the womb out and incising it on its posterior surface for the extraction of the child.

Lodgment of a Hair-Pin in the Uterine Cavity in an Attempt to Produce Abortion.—Dr. E. L. PARTRIDGE related the following case, which he had seen with Dr. J. H. Nesbit: The patient was about twenty-four years of age, the mother of one child. She had had several miscarriages, which, presumably, she herself had induced. Having missed a menstrual period on the 5th or 6th of March, she introduced a hair-pin into the womb, the point downward. The pin slipped from her fingers

and entered the womb, where she allowed it to remain until it should produce some symptoms. On the twenty-seventh of March Dr. Nesbit was called, who found the os closed, but the cervix enlarged and exceedingly sensitive. The body of the uterus was also very tender to the touch. The patient up to this time had been walking about. There was no elevation of the temperature. A tupelo tent was introduced, and, on the next day, two larger ones were used. In the evening the patient passed several very offensive-smelling clots, and during the night she flooded very freely. On the 29th Dr. Partridge was asked to see her. According to her reckoning, it was now about the seventh week of pregnancy. The temperature was 105° F., the pulse 120 a minute, and there was evidently pelvic peritonitis. The cervix was pretty well dilated, and Dr. Partridge was able to touch the hair-pin with the finger. The patient was anesthetized, and, after fifteen or twenty minutes, he was enabled to remove the foreign body. The finger first came in contact with a mass within the cervix, which evidently was the greater part of the ovum, that had lost its vitality two or three weeks previously. Passing the finger up still farther, it came in contact with the two bars of the hair-pin lying in the right side of the uterine cavity, one prong being engaged in the walls at a slightly higher point than the other. An ordinary uterine dressing forceps was introduced, one bar of the pin was seized near its extremity, and, after a little manipulation, it became disengaged. The other point was then lifted and the hair-pin was removed. Remaining fragments of membrane were scraped out, an intra-uterine douche of bichloride solution was administered, and the patient was put to bed. He was told that the patient rallied very nicely from the operation. The temperature on the morning of the operation had been 105°, while in the evening it fell to 102°-6°. She continued to improve from that day, Saturday, until the following Tuesday, at which time the temperature had come down to 99°-8°, the pulse to 102. That night she left her bed, in spite of the remonstrances of the nurse, and walked the floor for about twenty minutes. The next morning she presented signs of extensive peritonitis, and died on the following Monday, nine days after the removal of the hair-pin. The highest temperature was 103°-8°, and the highest pulse rate 142.

The case was interesting because it was unusual, and verified the fact that women did sometimes successfully resort to mechanical means for penetrating the uterine cavity to bring on abortion in their own persons.

Remote Puerperal Hæmorrhage.—Dr. THOMAS related cases of this accident. (See page 253.)

Extra-uterine Pregnancy.—Dr. THOMAS related his further experience with extra-uterine pregnancy since he had read a paper upon that subject at the Boston meeting of the American Gynecological Society, in 1882. Within a short time he had seen his thirtieth case, which he believed to be an unusual number to occur in the experience of one man. Twenty-four of the cases had been reported in the paper already mentioned. He would rapidly run over the history of the remaining six. One he was requested to see by Dr. Ferdinand Beach. The patient had suffered from amenorrhœa for three months. One day, when she was about to get into a street-car, the driver whipped up his horses and she was thrown violently upon her feet. She was suddenly taken with pain, went home, and remained in bed, and, after six weeks, when Dr. Thomas was requested to see her, she had become extremely emaciated, the pulse was over 120 to the minute, and she looked like a person suffering either from pulmonary consumption or from diabetes—the last stage of the disease. Both he and Dr. Beach thought the case would prove fatal. The patient had been vomiting steadily, and had had repeated attacks of pelvic peritonitis. This was three months after the cessation of the menses, and six weeks after

the fall. He could not be positive about the diagnosis, but told Dr. Beach that there had been a pelvic hæmatocele or repeated pelvic hæmatoceles. The patient's appearance was that of a person who had been blanched by hæmorrhage. The hæmatocele might have been due to extra-uterine pregnancy. She was put under the influence of an anæsthetic and the aspirating-needle was inserted, whereupon what appeared to be undoubted liquor amnii was withdrawn. There was some question whether the fluid might not have come from a pelvic cyst tightly bound down by inflammatory material. The patient now began to suffer intense pain, and died at nine o'clock that night. The next day a post-mortem examination was made, and a fetus of three months was found. There were small masses behind the uterus covered over with lymph and clots of blood, so that one could readily trace where different ruptures had taken place, by the blood which had been poured out forming a kind of hæmatocele. The intestines were bound together by masses of lymph covering over the whole tumor. The case was unquestionably one of abdominal pregnancy, but one for which nothing could have been done in the way of surgical procedure at any time when one would have thought of operating.

A short time after this Dr. Cushier requested him to see a lady who presented the following symptoms: She had become pregnant after a long period of sterility. All the symptoms of pregnancy existed. When she reached about the middle of the second month Dr. Cushier was called suddenly to see her, and found that she had been taken with a pelvic hæmatocele. She was entirely pulseless at the wrist, and the doctor recognized the rupture of an extra-uterine cyst at once. Although not expecting the patient to live an hour, she (Dr. Cushier) adopted the usual measures, and the patient rallied. Dr. Thomas saw her a few days later; at that time the pulse was very rapid, and all the symptoms of hæmatocele or of extra-uterine pregnancy, or of extra-uterine pregnancy with hæmatocele, existed. The doctor said the tumor was all the while increasing in size. It was believed that the patient was unquestionably pregnant, and the uterine cavity was explored with the curette, but it was found to be empty. The conclusion was then reached that a partial rupture of the foetal envelopes had taken place and was giving rise to hæmorrhage. Dr. Thomas regarded it as an exceedingly important point in extra-uterine pregnancy to recognize the fact that when partial rupture took place it did not necessarily destroy the child, nor was the rupture necessarily complete. This fact was illustrated by a case which he had once attended with Dr. Barker. A rupture had unquestionably taken place, for an hæmatocele was found. A post-mortem examination was made and the cyst was found to be perfect. It was distended to such an extent that one could look through its walls and see the fetus within. But a single vessel had ruptured, one of about the size of a knitting-needle, which had gone on pouring blood out into the peritoneal cavity until the woman, after four days of constant hæmorrhage, lost her life. This was a case in which the outer, muscular wall of the nidus had given way, while the membranes immediately surrounding the fetus were perfectly natural. The case of Dr. Cushier seemed to be one of this class. The faradaic battery was employed, one electrode being inserted within the rectum and the other applied to the abdominal surface. It was used one evening late, and the next morning there was a great improvement in the patient's condition. The treatment was continued, the mass subsided, and the patient entirely recovered.

The third case was seen with a surgeon of this city, in a patient who had been pregnant and was taken with symptoms of pelvic hæmatocele. Laparotomy was performed by the surgeon in charge. The patient died, but nothing else, however, could have been done for her.

The fourth case he saw about three weeks ago with Dr. Cocks, of Harlem. It was unquestionably a case of extra-uterine pregnancy, as the foetal mass could be felt to one side of the uterus, and the uterus itself could be distinctly mapped out on the other side. The cervix felt like that of a pregnant woman. The patient had never before failed to menstruate, and there were the usual signs of pregnancy in the breasts. Ballottement could be distinctly obtained in the foetal sac. She suffered from bearing-down pains, like the pains of abortion. The electrical current was used, and the patient began to improve immediately. There was a rapid subsidence of the tumor, and complete recovery had taken place.

The fifth case he saw about ten days ago, with Dr. Henry Griswold and Dr. Jewett. The patient had had one child years before. The only peculiarity about the present pregnancy, she said, related to the movements of the child. The ninth month having passed, she sent for Dr. Jewett, who found everything normal except that labor pains were terrific and there was no dilatation of the os. He remained with her twenty-four hours, and the labor pains gradually ceased, but still the os had not dilated. Dr. Griswold was sent for. The woman now declared that the child was dead, as she had up to this time felt its movements plainly, while now it was perfectly still. Dr. Griswold put the patient under an anæsthetic, dilated the uterine canal, inserted the whole hand into the vagina, introduced the index-finger completely into the uterus, and found that organ entirely empty. He then passed a large sound and found nothing except a little decidual membrane. The sound entered about four or five inches. When Dr. Thomas saw the patient he was able to introduce the finger into the uterus and verify what Dr. Griswold afterward told him had been his experience. He could feel the head of the child very distinctly through the vagina at the side of the uterus, but, unfortunately, the child was dead. Labor had come on, as it usually did in such cases, at term, and, no means being afforded for the escape of the child into the external world, it had died. But in one case, which came under the care of Dr. Jessup, of England, the condition had been recognized in time, an abdominal incision was made, and both the woman and the child were saved. Another case occurred in the practice of Dr. King, of Edisto Island, in South Carolina. Labor came on at the ninth month. Dr. King made an incision through the vaginal walls, applied a pair of forceps to the head, which was presenting, extracted a living child, and the mother recovered. In the present case the woman was in a similar condition, the only difference being that the child's interests had been sacrificed and the mother's alone remained to be considered. Dr. Thomas believed that surgical interference was not justifiable so long as the woman's health remained unaffected, and advised that she be allowed to go about her affairs until something should take place within the peritoneal cavity demanding interference. He had seen three such cases. In one case he had removed a full-grown child at the Woman's Hospital.

In another case, that of a woman living on Eighth Avenue, he removed a child weighing eight pounds, at the eighteenth month of abdominal pregnancy. In still another instance, that of a negress, sent to him by Dr. Young, he removed a child from the abdominal cavity weighing nine pounds, pregnancy having taken place eighteen months before. All three of the patients recovered. In the case now under observation, as in the other cases, the longer the fetus and its envelopes remained in the peritoneal cavity, the more would they be found to have undergone absorption and contraction, and the less would be the danger attending their removal. If they should begin to undergo decomposition and pus should form, an operation ought to be done without delay.

He had now related the histories of five cases of extra-uterine pregnancy seen the present season, and he believed that the conclusion which he meant to draw from these and the remaining one, which he would mention, was a perfectly legitimate one, namely, that in this condition surgical interference was to be avoided by every means in our power. He himself had three times tapped the tumor with a needle, in each case with a fatal result. These cases had already been placed upon record.

So far as cutting down upon the mass and removing it was concerned, every one knew what had so far been the result. We had reasons to suppose, however, that with antiseptic methods the future should give greater results from this procedure. But he had met with such wonderful results from the use of electricity that he must express his views loudly in favor of the adoption of that measure in every case in which a diagnosis could be made in time. One great advantage it possessed was that, in case it did no good, it could not do any harm.

The sixth case was that of a lady living out of the city, of whom Dr. Lambert, of Greenwich, N. Y., wrote to him. Dr. Thomas had treated the patient for sterility a short time before in his private hospital. She had gone away and become pregnant. Her physician said she had been pregnant for five months, and that something was wrong, but he was unable to decide what. She was brought to New York, and Dr. Thomas visited her, and found the uterus larger than normal, but evidently empty. He found what he believed to be a small fetus behind the uterus in the abdominal cavity. Dr. Jones was asked to see the patient, and, after making a careful examination, returned and told Dr. Thomas that he was confident the woman had an extra-uterine pregnancy; that he had explored the uterine cavity, and was perfectly satisfied of that fact. A consultation was held, to which Dr. Barker was added, and a great diversity of opinion existed with regard to the exact nature of the case. But it was decided that electricity should be employed, and within a few hours after its use there was an improvement in the symptoms; and within two months the tumor had almost entirely disappeared, so that the lady was up and riding about the country on horseback. The ground which Dr. Thomas took with regard to the employment of electricity was that it could do no harm. The patient was pregnant, and if, as some of the gentlemen supposed, the fetus was within the uterus, it could do no more than produce abortion, which would be perfectly justifiable, considering her physical and mental condition. Dr. Thomas, however, had had no doubt with regard to the existence of extra-uterine pregnancy.

Dr. R. WATTS asked whether, if there were rupture and active hemorrhage in a case of extra-uterine pregnancy, there would be any other remedy than laparotomy.

Dr. THOMAS said he would open the abdomen immediately under such circumstances.

Reports on the Progress of Medicine.

CUTANEOUS AND VENEREAL DISEASES.

By EDWARD BENNET BRONSON, M. D.

Leprosy in Brazil.—Dr. J. McF. Gaston, who for a number of years resided upon the coast of Brazil, gives an account of his observations of leprosy in this region in the "New Or-

leans Medical and Surgical Journal." The medical faculty of Brazil, it is stated, regard the disease as contagious—as much so even as variola—and in many parts of the country *Uproseries* have been established outside the city walls, to which are consigned all lepers excepting those of the very wealthiest families. These hospitals are supported by the government. It is believed that hereditary influence plays an important part also in the production of leprosy, on account of the numerous instances in which children of leprosy parents become lepers. The conviction of the people that the disease is propagable from husband to wife, or *vice versa*, leads to the interruption of conjugal relations so soon as the disease appears in either one. When special hospitals do not exist, an affected member of a family is separated from the rest in a room apart, though often under the same roof.

The disease is not confined to any class of society, though people in the better walks of life are less subject to it than the humbler portions of the population living in the country. Contrary to the usual rule, according to Gaston's experience, leprosy was not found along the lowlands of that portion of the coast where he lived, but was frequently met with upon the elevated ridge just back of the coast, which in some places attained an altitude of two thousand feet. The only difference between the inhabitants of the two regions was that those upon the hills lived chiefly upon animal food, principally fresh pork, besides consuming a good deal of lard, while those of the lower lands along the coast lived upon fresh fish, together with an abundant diet of vegetables and fruit.

The disease begins, it is said, in most cases, with the appearance of anæsthetic pigmented spots upon the hands, associated with marked engorgement of the capillaries, giving them, when in a dependent position, a florid appearance, afterward becoming purplish, and finally of a bronze hue. After a few months tubercles make their appearance on the ears, nose, and eyebrows, the hairs of the latter falling out. Coffee-colored nodules appear later. The hands and feet become coffee-colored, with thickening and enlargement, which soon gives way to a shrinking of the tissues, forming characteristic depressions between the metacarpal bones of the thumb and forefinger. At this time there is usually a very considerable brownish discoloration of the ankles and the lower portion of the legs, but the rest of the body, which is protected by the clothing, preserves its natural appearance during the further progress of tissue degeneration about the face and extremities. Under the influence of depurative remedies, together with proper hygiene and diet, the disease may not, it is said, undergo any material aggravation for from one to two years; but, sooner or later, disintegration begins with ulceration and spontaneous amputation of joints, and finally death ends the scene. The writer believes there is no cure for the disease. In view of its tendency to become endemic in localities and of its probable contagiousness, he urges the importance of stringent measures being taken by the United States Government to exclude lepers from other countries, and to insist upon the absolute sequestration of those now here.

Neuritis in Zoster.—Dr. Dubler ("Arch. f. path. Anat. u. Physiol. u. f. klin. Med.," xvi, 1884) reports the results of the autopsies upon two persons who shortly before death had suffered from zoster. The first case was that of a woman, aged seventy-seven, who a year and a half before had had zoster of the region supplied by the eighth and ninth intercostal nerves, followed by recurrent attacks of neuralgia of the same region. The autopsy showed, besides the lesions of phthisis, a peristitis of the seventh, eighth, and ninth right ribs, upon which were three cheesy nodules in close relation to the sixth, seventh, eighth, and ninth intercostal nerves. These nerves, or their

branches, passed through the nodules to a greater or less extent, and only at the traversing part showed macroscopical changes—namely: thickening, adhesions to neighboring parts, and here and there reddening. Microscopical examination revealed a centripetal and centrifugal neuritis of the seventh, eighth, and ninth nerves, while the sixth nerve showed only slight interstitial softening at the site of the nodule. The neuritis affected both the nerve-fibers and the connective tissue, extending to the muscular branches and to the nerves of the subcutaneous connective tissue. The spinal ganglia of these nerves, the spinal cord, and the sympathetic were unaffected. On the left side there was a diseased ganglion.

The second case was that of a woman, aged seventy-one, who had had a zoster over the lower intercostal region, followed by neuralgia, some three months before death. She died of a chronic double nephritis and a left-side pneumonia. Microscopical examination showed a normal spinal cord, and a neuritis of the ninth and tenth right intercostal nerves, with parenchymatous and interstitial changes. In the ninth spinal ganglion there were inflammatory alterations in certain parts where the nerve-bundles passed through; otherwise the ganglion was normal, at least so far as the ganglion-cells were concerned. In the absence of any apparent cause for the neuritis, the author calls this a case of spontaneous idiopathic zoster.

He maintains with regard to these cases that the hypothesis of a trophoneurosis is unnecessary, inasmuch as in both there was a direct extension of a neuritis to the skin. They further show, he maintains, that the neuritis of zoster may affect not only the sensitive, but also the motor nerve-fibers, which explains the fact that paralysis may be associated with zoster.

As to the etiology, Dubler maintains that anything capable of producing a neuritis may cause zoster. Hence, it may arise in consequence of traumatism, extension of inflammation in neighboring parts, from certain toxic agencies—such as carbonic acid, arsenical poisoning, and infectious miasms—from rheumatism, or, on the other hand, it may be due to a spontaneous neuritis.

Comedones in Children.—One might infer, from the account given in most treatises on diseases of the skin, that comedone were never met with until after puberty. Dr. H. R. Crocker ("Lancet," April 19, 1884) reports a number of cases in which "black heads" were observed in children. They generally appeared in locations subjected to heat and moisture, such as on the forehead under the hat-band. According to Crocker, comedones in children differ from those occurring in the adult in being mainly dependent upon local causes; in their greater tendency to form groups, the individual lesions being more closely set together; in their tendency to involve the hairy scalp; and in being readily amenable to treatment.

The Treatment of Lupus.—Schwimmer ("Wien. med. Wochenschrift," 1884, Nos. 20 to 22) strongly advocates the employment of pyrogallic acid and mercurial plaster for the treatment of lupus, and he gives a series of cases in which these remedies were followed by excellent results. The peculiarity of his plan is that the remedies are used in sequence, the action of one being supplemented by that of the other. He first applies vaseline to the diseased part till all crusts are removed, after which a ten-per-cent. ointment of pyrogallic acid and vaseline is applied, the dressing being changed two or three times a day and continued for from four to eight days, according to the activity of the process and the effect produced. Vaseline is then again used for a few days until the irritant effect of the acid is moderated, and then the mercurial plaster is applied and worn for from ten to fourteen days, the plaster being

changed two or three times a day if there is much discharge, otherwise only once a day. After two weeks, if any nodules are seen in the cicatrix, the same cyclus of treatment is repeated, beginning with the vaseline as before, but using the pyrogallic acid this time for only three or four days. Generally, the writer states, two courses will be enough to cure the disease, though in some cases a third may be required. The duration of the treatment by this method is said to be from three to four months.

Lupus of the Vulvo-anal Region.—Several cases of this form of lupus—which, perhaps, comes more often under the observation of the gynecologist than of the dermatologist—are reported by Macdonald in the "Edinburgh Medical Journal" for April, 1884. The importance of bearing in mind the possibility of the occurrence of lupus in the region of the perineum is urged on account of the liability of mistaking it for either epithelioma or syphilis. The differential diagnosis is made in the same way as when the disease occurs upon the face. It is described as beginning in the vulvo-anal region in the form of elevated tubercles, which break down and ulcerate. The general appearance of lupus in this location is similar to what it is upon the face, only the ulceration is more extensive and the cicatricial contraction greater and more disfiguring. In the writer's cases the disease crept over the anterior edge of the perineum and tended to extend a short distance into the vagina. While it invaded the perineal and vulvar regions very freely, it was slow to enter the vagina, and caused much less hypertrophy in the latter than in the former regions. The appearance of the disease upon the perineum was in one of his cases that of a shallow ulcer with distinctly indurated but not undermined edges. The writer expresses the opinion that lupus is neither a tubercular nor a strumous affection, but a local disease starting from some local irritation or injury, a history of which, in several of his cited cases, was obtainable. For treatment he advocates removal with the knife.

Pasty Applications in the Treatment of Skin Diseases.—In many inflammatory diseases of the skin, but especially in certain forms of eczema, ointments are not well borne. They are always dirty and difficult to remove, and in many cases tend to aggravate the irritation of the disease. Many substitutes have been proposed, among which, perhaps, Lassar's paste—consisting of starch, zinc, and vaseline—is most widely known, and has proved a most valuable addition to the materia medica of dermatology. Unna, who has made the subject of pasty applications to the skin an especial study, makes an interesting and useful report of his experiments in this direction in the "Monatsheft für praktische Dermatologie" (1884, iii). The first preparation which he devised, and which is commended on account of its simplicity and cheapness as well as of its excellent effect upon moist cutaneous diseases, is a so-called "bolus paste," composed of two parts terra alba and one part linseed-oil or glycerin. It can be quickly and easily spread upon the skin in a thin layer, where it soon forms a dry, closely adherent, and protective coating. Various substances may be added to this paste for the purpose of modifying its action, care being taken to first mix the white earth with the oil or glycerin before adding the other ingredients. The following formulæ are recommended, especially for eczema: Terra alba, five parts; ol. lini, three parts; liq. plumbi subacetatis, two parts. M. Or terra alba and ol. lini, each thirty parts; oxide of zinc and liq. plumbi subacetatis, each twenty parts. M. If instead of the terra alba the red Armenian bole is used, the color of the paste will approach that of the skin, which in some cases is an advantage. The bolus paste is recommended for all forms of eczema and for erythema, and as an excipient for strong oxidizing, reducing, or cauterizing agents.

Lead-pastes are prepared by boiling together fifty grammes of finely powdered litharge and eighty grammes of vinegar to form a mass of a pasty consistence, to which are then added ten grammes of linseed-oil or glycerin. The preparation is improved by boiling it a second or third time. It is said to be very useful in all sorts of eczemas. If the oil or glycerin is omitted, the paste has a remarkable drying effect upon the skin.

"*Kleister-Pasten*," or adhesive pastes, are composed of three parts rice-starch, two parts glycerin, and fifteen parts distilled water, the whole boiled down to fifteen parts. This paste is used as an excipient and will take up one half its weight of solid substances, and more than that if more glycerin is added. The drug to be used is mixed with the ingredients of the paste and all are boiled together. For eczema the writer recommends: R Zinc oxid., 50·0; ac. salicyl., 2·0; amyl. oryzae, 15·0; glycerin, 15·0; aq. destil., 75·0. M. Boil to 140·0. For acne the following formula is given: R Sulph. præcip., 40·0; calc. carbon. præcip., 2·0; zinc oxid., 20·0; amyl. oryzae, 15·0; glycerin, 20·0; aq. destil., 75·0. M. Boil down to 120.

Dextrin-pastes are made by mixing equal parts of dextrin, glycerin, and water, and boiling them together for a few minutes. If to this a powder is to be added, about one half more glycerin must be used. Thus, for eczema the following formula is given: R Zinc oxid., 40·0; dextrin, 20·0; aq. destil., 20·0; glycerin, 40·0; flor. sulph., 2·0. M. Sig. Boil together to make a paste. Another formula for eczema is a mixture of the lead and dextrin pastes made by boiling litharg., 30·0, and vinegar, 50·0, together to make 50·0, and then adding 15·0 each of dextrin, water, and glycerin, previously boiled together, and boiling the whole till a paste is formed. If a fluid substance is to be added to the dextrin paste, such as the liq. plumb. subacetat., no water need be used.

"*Gummy-Pasten*," or mucilaginous pastes, are made with gum arabic as the adhesive principle. A cheap and harmless one, that sets quickly, is made by mixing one part each of mucilage of gum arabic and glycerin with two parts of an indifferent powder, such as starch. To it may be added various medicaments, it being specially useful as an excipient for chrysarobin or pyrogallic acid. If the powder is omitted, the other ingredients form a quickly drying liniment, well adapted for the use of carbolic acid, etc., in pruriginous diseases. This preparation, it is said, does not allow of so extended use as other forms, for all acids that tend to injure the adhesive quality of the gum spoil the paste.

According to Unna's experience, lead should only be used in the "lead paste" in the form of the acetate, or in a mixture with "dextrin paste." Zinc oxide could be used in all of the preparations. Sulphur was not well tolerated by the bolus paste, and not at all by the lead paste. Ichthyol combined well with all except the gummy pastes; tar with the starch, dextrin, and gummy preparations; and naphthol, carbolic acid, chloral, and camphor with all; and the same was true of salicylic acid, except that with the gummy paste it could be used only in the reduced strength. Iodine and iodoform combined with all excepting the starch and dextrin pastes. Corrosive sublimate, calomel, and the red and white precipitates went well with all, while chrysarobin and pyrogallic acid were best combined with the bolus and gummy pastes. Animal, vegetable, and mineral fats and soaps, though they could be used with all in small quantities, yet, when added in large proportion, were, with most of the pastes, incompatible.

Resorcin in Diseases of the Skin.—Dr. J. Andeer, one of the first to advocate the use of resorcin, writes enthusiastically concerning its beneficial effects in diseases of the skin (*Ibid*). The action of the drug was best exhibited in diseases affecting

the epidermis of the skin, or the epithelium of the mucous membrane. Used topically upon the sound skin, it produced absolutely no unpleasant effect, neither abnormal stiffness, discoloration, roughness, nor scaling. Though it is not absorbed by the normal skin, absorption takes place quite readily, it is said, when the skin is in a pathological condition. The method of using the resorcin was by innunction, a five- to eighty-per-cent. ointment being used, made with vaseline. The results reported by Andeer are most extraordinary. Among the diseases asserted to have been cured by it are scarlatina, rubella, measles, variola, vaccinia, eczema, fissures at mucous orifices, frost-bite, syphilis, anthrax, and even leprosy. In scarlet fever the writer used a twenty-per-cent. resorcin-vaseline, which was smeared over the whole body and covered with cotton batting. At the end of twenty-four hours all the unpleasant sensations of the patient had disappeared, and the temperature had become nearly normal. Like prompt results were obtained in a very severe case of measles by the use of baths combined with innunctions of twenty- to eighty-per-cent. resorcin-vaseline. A fifty-per-cent. vaseline effected a cure in a small-pox case in two days, the patient feeling entirely well in a week, without resulting scars. But a leprosy case was the most extraordinary of all. The patient, a woman, who had been leprosy for a long time, with thickening of the skin, tuberculous formations, ulceration, etc., was rubbed every second day, each time in a fresh spot, with the most concentrated resorcin-vaseline, and in four weeks all her distressing symptoms had disappeared. More acquaintance with this most remarkable remedy is much to be desired.

The Extirpation of Small Round Tumors of the Skin with a Quickly-rotating Punch.—Instead of using an ordinary knife for the removal of little tumors of the skin, Dr. F. Busch ("Berl. klin. Wochenschr.," xxi, 1884) advocates the use of a steel punch which is made to rotate rapidly either by attaching it to the dentist's drilling engine, or, more conveniently, by fastening it to Fleureuloup's artificial leech. For different-sized tumors different-sized punches must be used, but, as this method is best adapted to small tumors of one centimetre diameter or less, the size of the punch need never be large. The instrument having first been adjusted according to the depth to which it is desired to cut, the punch is placed over the tumor, a spring is liberated, and in an instant the excision is made. A clean circular wound is left, which should be dressed in the usual manner for open wounds, and be allowed to heal from the bottom. When operating upon loose tissue, such as the eyelid, the requisite resistance is obtained by putting the part on the stretch—in the case of the eyelid, by inserting a piece of wood or horn under it. The lip should be supported by the finger. The advantages stated for this method are the simplicity of the operation and the avoidance of anesthetics.

The Elements of Diagnosis in Late Hereditary Syphilis.—Dr. Fournier ("Ann. de dermat. et de syph.," 1884, Nos. 3, 4, and 5) summarizes the various symptoms by which in an obscure case we may arrive at a diagnosis of late hereditary syphilis. The more essential factors upon which such a diagnosis will depend are stated as follows:

1. *Constitution*—a factor, however, which is not regarded as especially important. The subjects of hereditary syphilis are usually delicate, thin, muscularly weak, with a pallid or rather grayish and almost earthy complexion. The latter is often confounded with the complexion of struma, but in syphilis the fine, pale, transparent skin, the massive hypertrophy of the upper lip, the lividity of the extremities, the goose-flesh of the extensor surface of the limbs, and the chronic acne that characterize the scrofulous patient, are wanting.

2. *Arrest of Development*.—Syphilitic children develop slowly, walk and speak late, are retarded in their growth, do not attain

the average height, are undersized and mal-developed in all proportions. This slowness and incompleteness of growth affect the testicle, the hair of the beard, pubes, etc., and in women the establishment of menstruation is retarded and the breasts develop poorly.

3. *Deformities of the Skull and Nose.*—The deformities of the skull most commonly affect the frontal bone, and present three varieties: 1. The bone projects prominently *en masse*, being higher and longer than usual and more curved forward. In some cases, instead of forming a gentle curve from the eyebrows to the hair, it rises vertically or projects forward so as to form an obtuse angle with the root of the nose. 2. A more frequent deformity is the production of lateral bosses, which are rounded and almost invariably bilateral and regularly symmetrical. 3. A very much rarer variety of the deformity is a vertical boss in the middle line of the bone, generally two to three centimetres long, apparently flattened at the sides, and projecting in front like a chicken-breast. The deformities of the other parts of the head are described as of four kinds: 1. Small, flattened, nipple-like elevations of the bone, circular in shape and convex. They are of bony hardness, the skin over them is unaffected, and their size varies up to that of a twenty-five-cent piece. They are usually lateral and symmetrical. 2. Transverse enlargement of the skull, caused by lateral prominence of the parietal bones. Sometimes there is a depression over the sagittal suture, while the skull is prominent at the sides. 3. Asymmetrical skull. 4. Hydrocephalic skull, which often is very slight.

The *deformities of the nose* are of two varieties: 1. The nose is enlarged and disfigured, presenting a caved-in appearance, or otherwise misshapen and grotesque. This deformity is due to destruction of the septum, occurring in childhood or adolescence, and is attended with a history of *ozæna*, discharge of detritus, etc. 2. More commonly the deformity is slight and hardly appreciable, producing rather a badly formed nose than a decidedly deformed one. Most usually just below the frontal spine the bridge of the nose is depressed and flattened, and its base is widened. In other cases, but more rarely, the deformity affects the inferior segment of the nose, giving rise to inequality of the surface and slight depression at the sides. This condition dates from birth, and may be intra-uterine.

4. *Deformities of the Bones of the Trunk and Limbs.*—These are of two varieties, viz.: First, circumscribed lesions, consisting in tumefactions and osseous swellings, producing modifications both of structure and shape. This variety is seen most frequently in the long bones, affecting either the shaft or extremities, as, for example, in dactylitis. The tibia is the most characteristically affected bone, sometimes showing thickening and enlargement for one third its entire length. Sometimes its surface is uneven, irregular, and covered with nodes; sometimes the crest becomes broadened and flattened, so as to form a plane surface rather than a crest; sometimes it shows a marked incurvation on its anterior ridge, which is not due to curvature of the bone but to a partial hyperostosis. In a second class of cases a general enlargement of the bones is met with, sometimes affecting only one bone, sometimes a whole system, such as the bones of the spine. Besides this we find incurvations of the bones of the extremities, deformities of the thorax, and spinal rickets. While syphilis is not a direct cause of rickets, it gives rise to it through the general enfeeblement of the constitution, which is superinduced by the disease.

5. *Cicatrices of Skin and Mucous Membrane.*—While many of these are of indefinite diagnostic value, they often possess certain characters affording presumptive evidence of syphilis. These characters are, first, large extent of the scars, especially when they appear in considerable number. A second and more important character is configuration. The scars are rounded, have

their borders made up of many segments of circles, or they are serpiginous in form. A single semicircular scar is very characteristic. A third character relates to the seat of the cicatrices. They are found at the angle of mouth, on the nose, preferably on the ala and below the septum, on the lower part of the back and buttocks, and the posterior crural region, where they are very faintly marked and have to be carefully sought, and finally on the palate and pharynx.

6. *The Lesions of the Eye.*—In the first place, there is apt to be a history of antecedent ocular inflammation which was very severe and affected both eyes successively. This antecedent inflammation leaves its traces in impaired transparency of the cornea in the form of leucomas; in lesions of the iris in the form of synechia, with irregularity in dilatation of the pupil; or of deposits of false membrane in the pupillary space. More rarely we find atrophic spots in the choroid, papillary atrophy, and very rarely zonular cataract. Of especial frequency are diffuse interstitial keratitis and iritis.

7. *Lesions of the Ear.*—There is antecedent purulent discharge attended with the various results of suppurative disease of the middle ear. As evidences of the previous disease we have alterations of the tympanum, such as perforations, cicatrices, partial or complete destruction of the membrane; in some cases complete or partial deafness of one or both ears without apparent lesion. The deafness may be recognized as syphilitic when produced without local or general symptoms of otitis vulgaris; when it comes suddenly, progresses rapidly, and becomes confirmed in an extraordinarily short time; when it is very marked and is permanent; when it occurs without appreciable lesion.

8. *Dental Deformities.*—For these the writer refers to a previous article in Nos. 9 and 10 of the "*Annales de dermatologie et de syphilis*," 1883.

9. *Lesions of the Testicles.*—In the first few weeks, months, or years of life, according to Fournier, the testicles may present the same lesions as in acquired syphilis of adults, in the form either of inflammation of the tunica albuginea or of sarcocele. The disease runs the same course as in adults. If treated, it may be healed; if not, atrophy sets in. It is generally double and symmetrical. It is so apt to be overlooked in children that it is commonly left untreated, and, consequently, the testicles atrophy, so that, in advanced age, we often find the latter very small, of a peculiar hardness, irregular in shape, nodular, and without antecedent history of disease. This condition constitutes a valuable sign of hereditary syphilis. In a much smaller proportion of cases there will be found in advanced years a relative atrophy or impaired development, in which the testicles are notably small, but not deformed, and without morbid induration. They are like a child's testicles, and are not the result of pathological processes, but due simply to an arrest of development.

It is further observed that subjects of hereditary syphilis are often affected with ganglionic hypertrophies more or less marked, which are generally most noticeable in the lateral regions of the neck—sometimes in the inguinal region, in the axilla, or in the abdominal cavity. They are of long duration, and are hard to the touch. Very often these glands are regarded as strumous in character. Chronic hydrarthrosis, especially affecting the knees, and deforming arthropathies, are also sometimes met with. Moreover, the disease may cause an arrest of intellectual development, and sometimes complete idiocy. The mental impairment may be associated with motor derangements, attended with more or less uncertainty or clumsiness of movement. Finally, in other cases that are obscure, the family history, especially a record of many miscarriages and the early death of several children of the family, will assist in guiding us to a correct diagnosis.

The Abortive Treatment of Soft Chancre.—Such is the promising title of a paper by Hans von Hebra ("Wien. med. Presse," xiv, 1884), in which are reported ten cases of non-infecting chancre successfully treated by local applications of salicylic acid; though, so far as they go, the results are excellent, the number of cases is far too small to warrant general conclusions. The method consisted in applying pure salicylic acid directly to the ulcer, care being taken not to allow it to touch sound parts, after carefully washing the affected member with warm water. The acid is covered over with a piece of lint, and a strip of adhesive plaster is placed over all. We are cautioned to wash off any remains of previous applications—as of lead, zinc, or mercury—with soap and water, since salicylic acid is liable to combine with these substances and prove more caustic than we wish. If the ulcer is of a mild type, the dressing need be renewed but once in twenty-four hours; but, if there is a good deal of secretion, it should be changed twice a day. During the first day the ulcer covers itself with a white scab, while the surrounding parts become red. After the third day, by which time the scab attains a considerable size, the use of the acid must be stopped. The subsequent treatment consisted in the use of some emollient ointment, under which the scab became detached in half a day, leaving a healthy raw surface, which healed in from two to three days. The writer states that by this method the sore heals in as many days as it takes weeks to heal it by other methods. The treatment is said to be almost painless, and is also very cleanly. In none of his ten cases were there any buboes. [It may be mentioned that this same method of treatment was in use in this city five or six years ago.]

A New Preparation of Mercury.—A new mercurial preparation, to which the name *hydrargyrum tauricum oxydulatum* has been given, is described by its sponsor, Dr. G. Lustgarter ("Wien. med. Wochensh.," 1884, Nos. 11 to 14), as a dark, yellowish-green, odorless and tasteless powder, which does not change by keeping, and is easily assimilated when administered by the mouth. The dose is one tenth of a gramme, and is given with milk-sugar in capsules, one half to one hour after meals. The iodide of potassium, it is stated, can not be safely used at the same time, on account of the danger of too large an amount of the iodide of mercury being formed. It is asserted of this preparation that it is not liable to cause stomatitis or salivation, nor to give rise to any trouble in the digestive tract. Its action in syphilis, in the few cases in which it was tried, is described as favorable.

Miscellany.

THERAPEUTICAL NOTES.

Hydrastis Canadensis in Gynecological Practice.—Dr. Edgar Kurz, of Florence, contributes a short article to Betz's "Memorialien," in which he summarizes Schatz's statements in regard to the effects of the drug, and briefly recounts his own experience with it, having employed the fluid extract made by Messrs. Parke, Davis & Co. The first case was one of profuse menstruation in a girl fifteen years old, in whom menstruation had been established six months before. Twenty drops were given three times a day, beginning fourteen days before the period. The first flow was perceptibly moderated, and the continued use of the remedy for a few months rendered the performance of the function perfectly normal. The second case was one of slight metritis and oöphoritis. The flow always occurred several days too soon, and lasted fifteen days, so that the patient was very much weakened. The use of hydrastis was followed by a restoration of the flow to the proper character.

but the other features of the case were unaffected. The third case was one of a large interstitial fibrous tumor with hemorrhages at irregular intervals. After several weeks' daily use of hydrastis the flow returned only once in three weeks, and, after a few months' continuance of the remedy, only every four weeks, and the quantity of blood lost became normal. No diminution in the size of the tumor was observed. The fourth case was one of defective involution of the uterus after an abortion, with a profuse flow every three weeks. The use of hydrastis was begun eight days after the subsidence of a flow, and the next menstruation occurred at the proper time, and the loss of blood was diminished. The medication having been discontinued, the next flow came in three weeks, but a resumption of the use of the hydrastis caused the patient to become regular again. The fifth case was one of chronic oöphoritis, with moderate losses of blood occurring quite irregularly—every eight to fourteen days. The use of hydrastis caused the flow to appear regularly every three weeks. The sixth case was one of prolapse and retroflexion of the uterus, the organ being soft and easily brought into a state of ante flexion. Menstruation was profuse and anticipating, and the patient had hystero-epilepsy. The use of fifteen drops of the fluid extract of hydrastis three times a day was begun fourteen days before an expected period. The flow soon became regular and less profuse, but each menstruation was still accompanied by a hystero-epileptic attack until a Hodge's pessary was inserted. The seventh case was one of chronic metritis and endometritis, with profuse menstruation lasting ten days. A prolonged use of hydrastis reduced the duration of the flow to four days, and at the same time the leucorrhœa was decidedly diminished.

Osmic Acid in the Treatment of Epilepsy.—Wildermuth ("Berliner klin. Wochenschrift;" "Centralbl. f. klin. Med.") has experimented for the past two years with osmic acid as a remedy for epilepsy, using pills of osmate of potassium, each containing one one thousandth of a gramme of the salt. The largest amount given in a day was fifteen one thousandths of a gramme. The trials were begun upon ten confirmed epileptics. Seven showed no result; in two the attacks became less frequent; and in one, whose case was apparently quite desperate, a most astonishing change took place, consisting of a prompt diminution in the frequency and severity of the attacks, and their final disappearance, together with an improvement in the mental condition. Of three patients with whom the osmic-acid treatment had only recently been begun, two showed perceptible improvement, and in the third no effect was noticed. In none of the cases were any evil effects observed.

Naphthalin in Diarrhœal Affections.—At the third German *Kongress für innere Medizin* ("Centralbl. f. klin. Med.") Dr. Rossbach called attention to the fact that large doses of naphthalin might be given without producing poisonous effects, inasmuch as nearly the whole of it passed through the intestinal canal unchanged, although in some cases a small amount of it, either in its own form or changed into naphthol, was to be recognized in the urine. The latter fact, he said, made the remedy of value in preventing putrefaction of the urine. He had found the drug of service in almost all forms of diarrhœal disease, provided it did not depend on some incurable affection like carcinoma. In the vomiting and purging of children, however, it did not seem to be of any avail. Patients soon became accustomed to the smell of the medicine, and there were only a few whose digestive organs would not tolerate it.

The Rearing of Hand-fed Infants.—In a lecture on this subject, at the London International Health Exhibition, an abstract of which we find in the "Lancet," Mr. Edmund Owen remarked that probably almost every one would agree to the general proposition that for the first half year of infant life the mother's milk should be the only food; but where a poor woman had to leave her infant in order to earn money for the support of her husband, or where the lady of fashion found that the claims of society were so strong as to efface the sweet duties of motherhood, the question had to be answered as to the best artificial food. The physiological chemist brought in his answer: having made an analysis of human milk, he prepared a patent food which, he thought, ought to be even superior to the original article; but his compound was never absolutely fresh, and, when reared on it, infants were too apt to grow weak and flabby; most likely it contained some starchy element which

found no representative in human milk; he might almost as well put in fine sawdust.

The lecturer was apprehensive lest preserved milk should entirely usurp the place of fresh milk in the nursery. At present it was far too widely employed, and he entirely failed to see how it could form a more wholesome diet for infants—as some maintained it did—than the fresh article. He could no more believe this than that the adult would thrive better on canned American meat than on fresh sirloin. For babies, cow's milk, which should be always fresh, should be mixed with an equal or even greater bulk of warm water, in which a lump of white sugar and a pinch of salt had been dissolved; the fresh milk was an excellent antiscorbutic, and was therefore always needed. Often, when he had been assured that cow's milk could not be retained by the infant stomach, he had been able to demonstrate to the contrary by mixing even as much as double the quantity of water with it. In summer lime-water might be added to the mixture.

As regarded feeding-bottles, Mr. Owen said that the old-fashioned long, straight one, with the short India-rubber nipple, and with no tube at all, was the best; and he wished that, in their search for the antique, mothers would revert to the use of the ancient feeder. With this the infant could be fed only when the nurse had the bottle in her hand, so that the child's meals would be given at regular intervals for a definite time, and under close watching. The very worst kind of feeder was that now in general use; he had heard it called, by one well competent to form an opinion on the matter, "the lazy nurse's bottle." It was not so easily kept clean as the slipper-bottle, and was liable to many and serious abuses. Infants should be fed at regular intervals, and, if they vomited after their milk, they should be fed on smaller quantities, given at shorter intervals. As a rule, for the first month the bottle should be given every two hours, gradually increasing the interval to three and eventually to four hours. As time went on, less and less water should be added to the milk. Too often infants were fed simply because they cried. True, the infant had "no language but a cry," but the cry might mean that the stomach was already overloaded. Before the end of the first year infants should be entirely weaned from the bottle; they should then have daily a little undercooked meat pounded into a pulp, to which some gravy and salt had been added. Potato finely mashed and covered with gravy, an egg, or a little milk pudding, might vary the diet. But on no account should they be allowed any wine, beer, tea, or coffee, though they might have cocoa and milk. The meals should be given regularly; children should not be allowed to "pick" at bread-and-butter, cakes, and sweetmeats in the intervals.

Having criticised unfavorably the absurd fashion of bunching all the little child's clothes around the middle of its body, the lecturer pleaded that here, at any rate, there was great need for a "scheme of redistribution." The body should be evenly covered. Children could not be hardened by cold baths or by any other exposure to cold; only the very fit could survive such severe treatment. Like flowers and fruit, they loved warmth and sunlight; and when he had a sick child under observation he made it one of his first cares to have the cot placed in a sunny part of the room. In England people did not seem to know the value of sunlight; the Italians did, however, and their common saying was to the effect that "where the sun does not go the doctor does." The sun's rays had a destructive influence on suspicious or baneful gases; but to such vapors children should never be exposed. No bath, sink, or closet should be allowed near the nursery; many children fell victims to a neglect of this first law of domestic sanitation. Everything about them should be sweet and fresh, and there should be no carpets nor bed- or window-hangings to interfere with the free circulation of the air. On no account should the infant be taken to sleep in its mother's bed. If the weather was very cold, a warm brick or bottle wrapped in flannel might be tucked in under the clothes of the cot. For insuring appetite, digestion, and sleep, the infant should be taken out of doors each day when the weather was fine, and every day, unless a bitter wind was blowing, or it was foggy, the window should be thrown open for a while, as fresh air in the house was an absolute necessity. A well-managed babe should close its eyes as certainly as a mechanical wax doll as soon as it was laid down for sleep. The small hours of the night and the unhappy husband need never be disturbed by cradle-songs and lullabys. It was only a home-sick sugar-planter who cried, "Rock me to sleep,

mother!" and probably if an infant could speak it would never be heard repeating the request.

The Uncertainties of Therapeutics.—In the course of an address delivered at the opening of the section of medicine, at the recent meeting of the British Medical Association ("British Medical Journal"), Dr. James W. T. Smith, of Belfast, spoke as follows:

Our knowledge of therapeutics has not advanced in equal proportion with other branches of medical science. It is the department in which we know least. The modes of action of many medicines are a labyrinth to which we have no clew. To investigate their actions and to obtain a knowledge of their influence on disease are matters of great difficulty. The action of many is imperfectly known, and it may differ much in individuals. It is very difficult to estimate correctly what influence a medicine has really had in producing the changes which have occurred after its administration, for we know that many diseases will get well if left to themselves. Repeated trials and careful observation can alone determine this.

Perhaps there is no point on which members of our profession so frequently deceive themselves as on that of the effect of new medicines, and it must be admitted that many of the communications which appear in our journals upon this subject will not bear the test of experience. Such statements should be received with great hesitation, except when they come from those who, by careful physiological experiment, are entitled to speak on the subject. Another hindrance to progress is this—that, when a medicine has been ascertained to have a decided effect in a particular class of affections, there is a tendency to urge its employment and vaunt its usefulness in diseases over which it has no influence whatever; of this tendency the bromide of potassium is a good instance, that excellent but ill-used drug having been recommended in nearly half the ills which flesh is heir to.

New suggestions of treatment, and the wonderful effects of new medicines, put forth without substantial test, excite only distrust and disappointment in those who act on them, and add to the number of those who are already skeptical about the use of any medicine.

A disbelief in the efficacy of all drugs is, however, as unreasonable as an unlimited faith in their powers. We possess several which have been proved to have a definite action on which we can rely, and their number is being slowly added to. The discovery of salicylic acid has changed the whole treatment of rheumatism, and is a strong incentive to further therapeutic investigation.

After all, the practice of medicine is ultimately the practical application of therapeutic agents, and it is in the careful study of these that some of the greatest victories are to be gained by the coming race. But our progress must necessarily be slow, and we must take care lest the structures we build on our way prove only to be sand-castles.

The late Mr. Cæsar Hawkins.—Like the majority of those who have attained high rank in the profession of medicine, Mr. Hawkins was a man of character as well as ability. One who knew him for nearly fifty years writes of him: "During all these years he was ever the same—most industrious and painstaking in all matters relating to his work, high-minded and honorable in all that was connected with the interests of his profession, kind and liberal to a degree, that truly it may be said his right hand knew not what his left gave away. All who had the privilege of his friendship will indorse this estimate of his character. He was one of the most accurate and clear-headed of men that I had ever anything to do with; no lover of ostentation, no seeker after personal advancement by show or talk, but true in every sense of the word, and a thorough high-minded gentleman."—*Medical Times and Gazette*.

Murdock's Liquid Food.—"This American preparation," says the "Lancet," "is described as 'an extract of beef, mutton, and fruits, containing corpuscles and 12½ per cent. of soluble albumin.' The solution gives the blood-spectrum very strongly, and contains so much albumin as to become almost solid with dilute nitric acid. Of course, it is an exceedingly powerful and easily digestible form of food. It is calculated to be of the utmost use in medical practice; and, although the flavor is not very pleasant, it is not absolutely disagreeable, and may, no doubt, be modified by salt and spices. Among other applications, the use of the liquid food as an enema will strike every one."

Lectures and Addresses.

A CLINICAL LECTURE IN GYNÆCOLOGY,

DELIVERED AT BELLEVUE HOSPITAL.

By WILLIAM M. POLK, M. D.,

PROFESSOR OF OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN IN THE
MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

*Vaginal Cystotomy in a Case of Paralysis of the Bladder, with
Remarks on Catheterization of the Ureters.*

This case, gentlemen, is that of a woman, about twenty-eight years old, who a year ago fell from a third-story window, sustaining injuries to the spine which resulted in paraplegia. She was admitted to the hospital two months ago. As is usual in such cases, there was paralysis of the bladder and rectum. An additional feature of interest is the fact that menstruation was also suspended. The paralysis of the limbs has now been cured four months, and the rectum, though performing its functions somewhat sluggishly, has greatly improved. The paralysis of the bladder and the suppression of menstruation continue.

First, as to the bladder. There is a constant dribbling of urine, with all the annoyances arising from it, such as the discomfort of the wet state, the excoriation resulting from the action of the urine, and the ever-present offensive odor. In addition, there is constant pain in the region of the base of the bladder. The urine is loaded with pus and mucus, contains myriads of vibrios, and is highly alkaline.

Passing the finger into the vagina, we find the uterus and ovaries normal, but between the anterior vaginal wall and the symphysis there is a rounded, sensitive tumor, in size about equal to an egg. Passing the catheter through the urethra, we find this tumor to be the bladder, and, as you see from the absence of any flow of urine, the empty bladder.

With the instrument in the organ and my finger in the vagina, I can carefully explore its base and sides, and, by placing the hand thus above the pubes, I submit its upper parts to the same process. By this means I prove that there is no tumor or foreign body in the bladder, and that the mass between the anterior vaginal wall and the symphysis is nothing more than the organ itself, made prominent by its greatly thickened walls. Extensive hypertrophy of the walls of the bladder has been the result of the spinal injury.

Let me say here that, in making a vaginal examination, if a normal bladder is empty, you will find no prominence between the anterior vaginal wall and the symphysis pubis; the two surfaces can be brought into close relation, and the wall moved freely in all directions over the face of the bone.

Going back a little, we know from analogy that what has taken place in the bladder and its connections is the following:

The injury inflicted upon the cord by the fall expended itself mainly upon the lumbar enlargement, arresting for a time not only all action originating there, but all that

might have been sent from the upper portions of the cord and the brain. Gradually this lesion has been repaired for all the centers save those presiding over the bladder reflex and the function of menstruation. Paralysis of the bladder was not accompanied by paralysis of the urethra, for, as you see, this canal is tightly closed. Soon after the injury there was prolonged retention of urine, requiring the use of the catheter; after the patient left the hospital this gave place to dribbling of urine, for, as she had no means of relieving herself, the urine accumulated, distending the bladder, and finally forcing itself by mere weight through the resisting urethra.

As you may imagine, the vesical walls began to suffer from this constant distension; but, granting that they might not resent it, they surely would find it difficult to submit to the irritant action of the now decomposed urine. As a matter of fact, the combined influence of the over-distension and the irritation is shown in the hypertrophic thickening of the muscular and mucous walls of the bladder. Not only have the walls been thickened, but the capacity of the organ is much diminished. Whereas at first a quart of urine or more would be retained before dribbling set in, now four ounces represent its capacity. Does the mischief stop in the bladder? We know to the contrary; the resistance of the urethra extends beyond the bladder. If it is sufficient to cause the amount of hypertrophy and thickening witnessed here, it is sufficient to dam back urine through the ureters to the pelves of the kidneys, and set up double pyelitis with all its attendant dangers. The histories of these cases prove that such is the termination of this condition of the bladder, and, though our patient does not as yet give active evidences of implication of the pelves of the kidneys, that occurrence is a mere question of time.

Naturally we ask ourselves if this evil can not be averted. If this patient were under constant supervision, so that the urine could be drawn every two hours and the bladder washed out twice a day and fully distended, a great deal could be accomplished; but even this would not meet the difficulty so well as another procedure—viz., *opening the base of the bladder*. Make such an opening, and you relieve the bladder from its embarrassment. The urine flows off as fast as it is received from the ureters; the bladder, relieved of pressure and the decomposed urine, will grow no worse, but improve. And more than all—the pressure being taken from the ureters and pelves of the kidneys, the urine flowing off through the ureters as fast as it is formed, and decomposition and its results to the pelves being avoided—not only are the pressing dangers relieved, but we put the patient in the best position to escape those that lie directly in her way.

The cure that has taken place in the lower extremities—for the patient has entire restoration of their motor and sensory functions—and the great improvement she recognizes as having occurred in the rectum justify us in believing that in time improvement may occur in the action of the bladder; but, if she were to be left as heretofore, there is reason to believe that long before such improvement came the state of the kidneys would make it serve a short career

of usefulness. The same general treatment employed since her admission will be continued—tonics, galvanism, and faradization from the region of the bladder to the lower part of the cord, coupled with the occasional use of the actual cautery over the lower dorsal and upper lumbar regions.

While the patient is being anesthetized I will occupy you with some suggestions touching the second morbid condition—the suppressed menstrual function. Until the injury, this function had never suffered arrest; from that time till now it has been suspended. What is the cause? Unquestionably the injury to the spine, and the injury must have been low down, so as to sever the connection between the lumbar enlargement and the internal genitals, for we know that even after division of the cord in the dorsal region, *above the lumbar enlargement*, the processes of ovulation, of development of the pregnant uterus and the lacteal glands, and of parturition, may go on. If we may be allowed a conjecture, we will say that the lesion which has affected the centers presiding over the action of the bladder has likewise interfered with those presiding over the function of menstruation, and perhaps ovulation. It would be a most interesting study, that of the condition of this woman's ovaries. Is the development of the ova interfered with? Could we determine it in conjunction with a careful study of the cord, much light might be thrown upon the vexed question as to the independence of ovulation and menstruation. The two processes are so intimately associated, however, that it is probable any lesion of the cord affecting one would most likely affect both. But, whether ovulation is involved or not, menstruation assuredly is, for never since the injury has she given symptom or sign of such an occurrence. And just here let me again call your attention to the fact that we have no other cause of this cessation present. Supposing ovulation to continue, the question of pregnancy in this case must still be answered in the negative, for, in the absence of every evidence of uterine activity, even at the periods at which menstruation would fall due, we must conclude that here, at all events, the trophic changes in the uterus are so seriously impaired as to make the formation of a decidual membrane impossible. Without such a membrane the implantation and development of an ovum are highly improbable.

But the patient is now ready for the operation, so, with your permission, we will cease commenting upon these interesting but obscure topics and turn our attention to a matter of more immediate and practical importance to her and us. The point at which to make the opening is in the median line, half an inch above the vesical end of the urethra. We must bear in mind the relation of the ureters to this line, else injury may be done there openings. The injury itself would hardly cause much inconvenience, but subsequent contraction at the seat of injury might end in constriction or even closure of the tube—a matter of great moment. These openings are situated from half to three quarters of an inch from the anterior median line of the vagina, one on either side, and are about an inch and a half from the vesical end of the urethra. Our opening will, then, be so placed as to avoid injuring not only the ureters but the

vesical end of the urethra as well—a matter of less importance than lesion of the kidney outlets, but one bearing strongly upon the action of the urethra as an outlet—a question that may come up should the paralysis of the bladder be cured. The position of our patient is that upon the back with the thighs well flexed on the abdomen.

This blunt wire curette, having a large loop, will admirably serve our purpose as a guide. Introducing it into the bladder, I place the loop at the point selected for incision and press the vesical and vaginal walls down and out on a line with the ostium vaginae. You can easily feel the loop as I thrust this knife through the walls directly into it. Taking next this probe-pointed bistoury, I enlarge the opening toward the uterus so as easily to admit my index-finger. Owing to the condition of the walls, the bleeding is somewhat more than is usual with these cases, but even here it requires no special effort at arrest.

Carrying my finger well over the vesical wall, I appreciate the condition of the diseased mucous membrane. As intimated in the earlier remarks, it is thick, and thrown into folds; and off to the patient's right is a distinct pocket in the wall, free, however, of anything like stone formation.

As it is a matter of some importance to determine the condition of the pelves of the kidneys, and as the urine in the bladder is so infected with the products of vesical inflammation as to furnish us with no satisfactory evidence upon this point, I will collect some directly from the ureters by catheterizing them, and, at our next meeting, will give you the result of the inquiry.

We next wash out the interior of the bladder with a warm, saturated solution of borax, introduce this glass button, having a hole through it, into the opening, and return the patient to the ward. Should we leave the opening without the button, it would speedily close. To insure a permanent opening and give free drainage to the bladder, we must keep this perforated button in place for several weeks—perhaps as long as the paralysis lasts.

Our confident expectation is that this patient will improve greatly. Certainly she will be relieved from the drain and tension incident to a chronic cystitis, and possibly pyelitis, to say nothing of the relief given the kidneys by the free escape of the fresh urine.

We will keep the vagina clean, and for the present tend the bladder once a day with a warm solution of bichloride of mercury, 1 to 2,000, and chloride of sodium.

Before closing, permit me, gentlemen, to say a few words upon catheterization of the ureter. You have seen me do it upon this patient, after making the opening into the bladder, using a No. 5 instrument. Can it be done without such an opening? Yes. Simon did it by forcing the finger through the urethra, passing the catheter alongside and guiding its point with the finger-tip into the canal. The great objection to this procedure is that it usually results in permanent incontinence of urine—a very serious mishap.

Pawlick maintains that it can be done by following with the point of the catheter—the instrument being introduced through the urethra—certain lines on the anterior vaginal wall which indicate the course of the ureters as they enter

the bladder. He states that these lines can be made evident in all cases by carrying out the following directions:

The bladder must be empty, the abdomen free, the woman to be put in the knee-chest posture, and the perineum raised so as to distend the vagina with air. The lines are then seen starting from about the points at which we know the ureteric orifices to be situated, and running upward and outward, the course of each corresponding to that of the ureter.

There is no doubt that in cases of relaxed and distended vaginae these lines can be brought out, but in such as present contrary conditions you will as often fail to find them.

But, granting that they may be recognized in all cases, the great defect in the method is the difficulty attending the determination of the question as to the actual entrance into the ureter. The depth to which you may carry the instrument is but a poor guide. Many bladders are so elastic as to be carried before it, even so far as the synchronoses. Given a case in which catheterization of the ureter is demanded as a means of diagnosis—and every renal tumor requiring extirpation is such a case—Pawlick's method is too uncertain. Should the patient be a woman, open the base of the bladder, pass your catheter through the urethra, and, by means of your finger passed through the artificial opening, you can always insert the instrument into the canals. You collect urine first from one kidney, then from the other, and are in the only sure position to determine the state of the two organs. Should both be diseased, you spare your patient a fatal operation. Should one be sound, by operating you prolong life.

DRYNESS AND ELEVATION

THE MOST IMPORTANT ELEMENTS IN THE

CLIMATIC TREATMENT OF PHTHISIS.*

By CHARLES DENISON, M.D.,

DENVER, COL.

DRYNESS.

Synopsis: 1. Variability *versus* equability. 2. A rule for classifying climates as to dryness and desirability, based upon low, absolute, and relative humidities and preponderance of sunshine. 3. The influence of elevation, sunshine, cold, etc., in producing desirable dryness. 4. The physical effect of dryness on man.

The importance of the discussion of dryness is based upon the proposition: An actually small amount of atmospheric moisture is the most important element in the best climates for phthisis. Any proof of the correctness of this assertion will be deferred until after the consideration of the subject of dryness in its various phases as a climatic attribute. The statement, however, is thus prominently brought to the front because it is decidedly at variance with the past theories and beliefs of the great body of the medi-

cal profession. It is, therefore, to our advantage to start squarely and fairly by marshaling the forces that are thereby brought into controversy, for, as I shall show, the statement puts variability over against equability, and the latter has heretofore been the darling idea of the medical adviser—the delusive hope of the unfortunate consumptive.

It is to be regretted that the *preponderance-of-opinion* method of settling scientific questions in controversy controls the medical mind of to-day as much as it does. The method is at fault, for it establishes nothing. It simply asserts that a certain number of doctors think one way, and a lesser number, probably governed by much more valuable experience, think differently.

In the winter of 1873-'74 I made an effort to determine some unsettled climatic questions by thoroughly canvassing the experience of the medical profession. The result would have been satisfactory were it not for the foregoing criticism. Dr. J. H. Tyndale's late circular, the replies to which were summarized in the "New York Medical Journal," should have resulted in something more trustworthy, because of the later period and the character of the correspondents selected, as having some authority on the question of climate. But the criticism is still in force, and this association has much to do to bring the medical mind "down to bed-rock"—as they say out in the far West—down to something that is sure and settled, something we can pin our faith to and not be disappointed.

I shall endeavor to base the results of this analysis upon facts to be presented, if possible, in a new light, and supported by stated experience, so that your individual judgments will decide that the conclusions are well sustained.

It is to me a pleasing thought that, as scientific searchers after truth, your verdicts as to these conclusions will have no *political* significance, but will be given impartially according to the proofs presented, even though my decisions are contrary—as they will be—to the prevailing beliefs advanced by authors on the practice of medicine.

Instead of the relative humidity alone, I shall prefer the absolute humidity also—i. e., the number of grains of vapor to the cubic foot of air—as the criteria of dryness. The former is only relative at most, and very delusive, if the question of temperature happens to be forgotten. A cool or cold temperature, however, is the chief factor in the production of real dryness or low absolute humidity. It is, then, for me to defend *coldness*, *variability*, and *stimulation* as against their opposites, *warmth*, *equability*, and *enervation*, and to show, as I shall, that variability is the companion of dryness, and equability of moisture.

A definition is here needed as to what is *variability*, or its opposite, *equability*. To be sure, one place may be equable in your judgment that is more equable than another; but when a climate ceases to be equable and has become variable has not yet been definitely determined. In the absence of anything more definite, I should say the mean of inhabited climates as to changeability should be the line between *variability* and *equability*. I believe this is the only just line we can draw between the two forces placed in opposition. The fairness of this division will better appear as we proceed.

* Read before the American Climatological Association, May 8, 1884.

While altitude, wind, and exposure have much to do in determining the variability of a climate, I think I am right in saying the principal index of this character is the actual humidity. This real humidity is chiefly governed by temperature, for the air can hold invisible vapor in a rapidly increasing amount as temperature changes from cold to hot. From such conditions as solar influence, altitude, latitude, rain, radiation, winds, exposure, etc., the temperature of the air is determined; and these conditions, with temperature as their index, determine the atmospheric humidity. It is almost permissible, then, to say climate is absolute humidity, so much is the latter the key to every attribute of the former.

It is in harmony with this close association of temperature with actual humidity for me to propose the following subdivisions of climate, which I do on my own authority, and will ask you to accept them, that we may each of us have a clear conception of what the other means in speaking of dryness, equability, etc. I divide climate into four divisions:

1. Excessive dryness, } giving variability.
2. Moderate dryness, }
3. Moderate moisture, } giving equability.
4. Excessive moisture, }

Let us now continue the analysis so as to localize these divisions. The defenders of equability, according to the replies Dr. Tyndale received in the correspondence already referred to, would combine that quality with dryness, and some of them even with high altitude! My friends, take all the ground you choose, but do not be so generous to your side of the question as to leave us in doubt what you mean by the terms you use. You may have a great deal of *latitude*, but not much *altitude*. I will promise not to douse you under the level of the sea if you in turn will not force me to the top of Pike's Peak or to the region of the North Pole. We both of us prefer to remain where life can be enjoyed with a moderate degree of comfort. I, however, am willing to include the altitude of ten thousand feet for this latitude in summer, and you may include the torrid zone at sea-level in winter if you choose.

It has given me greater gratification than I can express to you to succeed in producing a classification of climates which I trust will merit your approval, as it is calculated to blot out the inconsistencies which have hitherto run riot in the medical mind. How this classification unfolds will appear as we proceed.

Right here I wish to acknowledge the favor conferred not only upon myself, but upon us all, by the Signal Service Bureau. They have furnished me the following statistics for the stations in the United States, one hundred and thirty-six in number, averaged, as I requested, by seasons—viz., the mean temperature, mean relative humidity, mean dew-point, mean cloudiness (scale of 0 to 10), mean maximum temperature, mean minimum temperature, mean daily range of temperature, mean monthly extreme ranges of temperature, mean inches of rainfall, mean vapor tension, and mean absolute humidity. I feel that General W. B. Hazen, Chief Signal Officer, and Lieutenant H. C. Dunwoody, assistant, deserve much of the credit for the valuable conclusions that are here obtained from these statistics.

Having thus at hand the absolute humidity for the United States, in grains of vapor to the cubic foot of air, I attempted to classify the climates, represented by each of the seasons, for the 45th, 40th, 35th, and 30th parallels of latitude, basing the divisions upon what I know of those climates as belonging to a fair proportionment for excessive dryness, moderate dryness, moderate moisture, and excessive moisture. I was happily surprised by the uniformity of increase in all my subdivisions from the lesser to the greater moisture, and the harmony these divisions seemed to maintain with the changing capacity of the air to contain vapor for equal divisions of temperature. In fact, after many other calculations, I found it took but very slight corrections to make all my subdivisions bear this relation to each other—viz., of the absolute humidity at saturation under 40 per cent. for excessive dryness, 40 to 60 per cent. for moderate dryness, 60 to 80 per cent. for moderate moisture, and above 80 per cent. for excessive moisture. As the absolute humidity depends upon temperature, isotherms were substituted for parallels of latitudes. The faults of these subdivisions were then neutralized by appropriate corrections for relative humidity and cloudiness, and the rule was found to work well for all places.

This first rule was as follows: The relative and absolute humidities and cloudiness in hundredths being known of a given place, find the grains of vapor at saturation either by working it out from the first two or by referring to the first two columns in Glaisher's tables (see Table I), and then take 40, 60, and 80 per cent. of this as the dividing lines between the four divisions of climate. Then correct the absolute humidity for the place to be rated by multiplying it by 100 plus the excess of the relative humidity above the mean 67 per cent., and plus the excess of cloudiness above the mean of $4\frac{1}{2}$ per cent., or by 100 minus these differences if they are below the means.*

Compare this result with the rating numbers already obtained, and the grade of the climate as to dryness is determined.†

Thus every climate is rated forward or backward from where its absolute humidity would seem to place it, according to its excess or deficiency of relative humidity and cloudy weather.

* The mean of 67 for relative humidity for the United States I obtained by several methods of computation; for instance, taking places on isothermal lines to represent the whole country, and also by comparing the fifteen highest with the fifteen lowest relative humidities for all the seasons. The mean of cloudiness was obtained by adding all the means together and dividing by the whole number.

† For instance, Los Angeles, Cal., has an autumn temperature of 64°, relative humidity 65·2, cloudiness 23 per cent., and absolute humidity 4·01 grains to the cubic foot. The capacity of the air to hold moisture at the temperature given is 6·54 grains. The rating divisions then are: Excessive dryness, under 2·64; moderate dryness, 2·64 to 3·95; moderate moisture, 3·95 to 5·27; and excessive moisture, above 5·27 grains. The correction for relative humidity is 02, and for cloudiness 21 per cent., which gives a rating number 2·83 according to the rule. This moves Los Angeles from moderate moisture back into moderate dryness, its more appropriate position for that season of the year, while Washington, D. C., with an absolute humidity of 3·73 grains, because of both relative humidity and cloudiness being above the mean, is rated forward from moderate moisture into extreme moisture for the same season.

While this rule worked nicely, throwing places of great absolute humidity, high relative humidity, or much cloudiness, proportionately to these excesses, toward the extreme of moisture, and those of opposite preponderance toward the extreme of dryness, according to their deserts, yet there appeared to be objections to it, as stated, which would not obtain with one dependent upon the unchanged records as given by the Signal Service. Besides, the necessity to carry out long computations for each place to be rated, and the possible charge that the rule given was arbitrary, finally led me to change the plan of classification to the following, which is based upon a definite proportion of the rating influence being given to each of the three elements which make up or indicate *dryness*—i. e., relative humidity, absolute humidity, and sunshine or cloudiness, its opposite, which we have definitely determined by the Signal Service. As nearly

TABLE I.

The Rating Table determining the Means of Dryness, made up from 67 per cent. of Saturation, 67 per cent. for Relative Humidity, and 44½ per cent. for Cloudiness, and obtaining One Third of their Sum. See Column (4).

57	48.7	100	19.84	132.93	81.0

as could be done, a third of the rating influence was given to each record indicating dryness or moisture, and the mean between these extremes was approximately determined to be 67 per cent. for relative humidity, 67 per cent. of saturation at the given temperature of the place for absolute humidity, to be expressed in tenths of a grain of vapor to the cubic foot of air, and 44½ per cent. for cloudiness, zero being no clouds and 100 constant cloudiness. Thus, for rating purposes, I constructed the foregoing table, based upon the means obtained.

In the last column (4) in this table we have the mean of relative humidity (67), the mean of cloudiness in hundredths (44½), and the mean of absolute humidity for different temperatures (see column 3) added together, and the sum divided by 3 to obtain the mean of all. By this last—the combined mean as to dryness or moisture—all places can be compared, the average temperature, relative humidity, absolute humidity, and cloudiness of which are known for a given time. The rule is thus simplified to a rating-table for all climates. For instance, Denver, for the autumn of 1883, with an average temperature of 50.4° F., has a rating mean, according to the table, of 46.3°; while the record shows relative humidity 50.1 and cloudiness 20 per cent., and absolute humidity, in tenths of grains, 18.9. A third of these three is 29.7. Denver, then, stands to the mean for the United States for that season as 27.7 is to 46.3, or 16.6 on the dry side of the mean. New York city, with temperature 53.9, has a rating number of 47.8, and with R. H. 69.9, cloudiness 51, and A. H. 32.9, gives a record of 51.3, or 3.5 on the moist side of the rating mean for that same season.

Thus continuing, all the seasons for all the Signal Service Stations in the United States were rated. I then found that twelve, or 12 per cent. on either side of the proper mean, would include nearly all the excesses or deficiencies. Only exceptionally moist or exceptionally dry places would exceed this limit. I therefore gave the first six excess or deficiency to *moderate moisture* and to *moderate dryness*, respectively; and the next six excess or deficiency to *extreme moisture* and to *extreme dryness*, respectively. The finally accepted *climatic rule for dryness* can then be simply stated thus:

With the combined mean of relative humidity and cloudiness per cent., and absolute humidity in tenths of a grain of vapor (see Table I [4]), compare one third of the sum of the actual records given of the same attributes for any place, and the difference, plus or minus, shows the rate of the given climate.

The question may be asked, Are you sure you have not been unjust to damp climates and too generous to very sunny ones in giving nearly one third the rating influence to cloudiness? I think not, most decidedly. The Signal Service estimates all over the country, both of temperature, absolute and relative humidity, are taken *behind the blinds*, and the wonderful influence of the sun, the source of everything that is good in climate, is literally "thrown into the shade" by what we have hitherto trusted as climatic records. This is a most important though a neglected consideration, especially in the clear air of such climates as are found in

* I. e., the difference between the mean maximum and mean minimum temperatures.

† Composed of the mean of relative humidity, cloudiness in hundredths, and absolute humidity in tenths of a grain of vapor to cubic foot, rated according to the rating table. Figures: 1 = Extreme dryness; 2 = moderate dryness; 3 = moderate moisture; 4 = extreme moisture. Letters a, b, and c = thirds of each division reckoned forward or backward from middle division 3. Six hundredths are given to each division, and the plus figures (1c+9, etc.) indicate the excess of certain places.

the western elevated plateaux, where the powerful effect of sunshine is quickly recorded by the metallic thermometer, and its absence as remarkably noted in the shade (see Diathermancy, farther on). Were it not that sunshine so often goes hand in hand with low humidity records, I should be in favor of giving it more, rather than less, influence in the rating of climates.*

To still further localize each climate with reference to others in the same division, I subdivided each of the larger into three smaller divisions, a, b, c, reckoning forward and backward from the middle line between moisture and dryness.

Thus, having rated over again all the signal stations in the United States, using figures, 1, 2, 3, 4, to designate the four divisions of climate, and the letters a, b, c, the appropriate thirds in each, I had ample source from which to choose proper climates to illustrate the discriminating operation of my rule. To make up the following table (Table II), I chose the driest five and the moistest five stations, and, besides these, five stations to represent each half of each division of climate, preferring those places which are well-known to climatologists, and which, collectively, besides fairly representing the whole area of the United States, have a somewhat uniform rating for the four seasons of the year.†

Besides the rating of each climate by seasons (see last column), the table contains all the factors which, with the rating means in Table I (4), are used in giving each climate and season its proper grade as to dryness. The nine columns contain the following means by seasons: Temperature, relative humidity, and absolute humidity, per cent. in tenths of grains to the cubic foot; dew-point and rainfall in inches; daily range of temperature, monthly extreme ranges of temperature, and rate of each climate expressed in figures 1, 2, 3, 4, and letters a, b, c, as described. (See page 286.)

As it is during winter chiefly that the invalid must have a change of climate, the classification for that season, accord-

ing to the rule, would give a very desirable table. The following table (Table III) is the exact rating for the year 1883, in order of dryness, the several divisions being separated into groups to indicate their position in the whole scale. Their mean temperatures are added, because temperature, a most important factor, is to have a separate consideration, according to the needs of individual invalids and the esteem in which different physicians hold the arguments in favor of a cool rather than warm temperature. Extremely dry places of widely different temperatures are, however, given, and by the aid of this and the preceding table one may make a choice, with definite reasons for his preference. (See page 288.)

While the great majority of signal stations are located in the moister sections of the United States, it is easily seen, by rating all stations for winter, that many are advanced toward the extreme of moisture by the relatively greater dampness due to the lowering temperature of that season. It is in winter that the minimum number of places are found in our first two, or dry, divisions—i. e., 13 in extreme dryness, 14 in moderate dryness, 38 in moderate moisture, and 71 in extreme moisture.*

Following out our plan of considering dryness as indicated by the amount of moisture in the atmosphere, let us see how this humidity is influenced by the varying conditions which make up climate—i. e., how dryness is produced. We will consider these conditions in the following order:

1. Dryness affected by temperature.
2. Altitude.
3. Latitude.
4. Seasons.
5. Distance from the ocean, etc.
6. Mountain ranges.
7. Absorbing power of earth.
8. Radiation.
9. Diathermancy.
10. Sunshine.
11. Absolute humidity.
12. Relative humidity.
13. Dryness indicated by variability.

* The rule takes into consideration temperature, absolute humidity, sunshine, and relative humidity—the four cardinal points in the climatic creed. Of course, altitude, exposure or location, forests and soil, are powerful modifiers to be considered in regard to their effect upon such a rule. We shall see further on how much these influences have already affected the actual humidity, and thus have their appropriate share in the rule. Especially is this the case with elevation, which I intend to show decidedly influences humidity, aside from its effect upon temperature, a fact which, I believe, has never been demonstrated by any one else.

† I ought to here explain that this last consideration of uniformity excluded from the table representative places in the extreme Northwest, as Fort Benton, Fort Custer, and Helena, Montana; Olympia, Washington Territory; Portland and Roseburg, Oregon, which are very generally on the dry side of the mean in summer, and decidedly on the moist side in winter and spring. With this exception, however, the fifty stations given in the table very fairly represent the United States.

The anomalies or extremes brought out by this method of rating are as follows for all the seasons of the United States Signal Stations: The greatest extremes as to dryness were Red Bluff and Winnemucca, Nevada; Visalia, California; and Eagle Rock, Idaho, for summer; El Paso, New Mexico, for spring, because of almost cloudless seasons of those places. The greatest extremes as to moisture were Spokane Falls, Washington Territory, Port Huron, Mich., and Rochester, N. Y., for winter, because of the high means of all the moisture indicating attributes for the low temperatures of that season.

* Of course, faults in the temperature and humidity statistics will greatly affect the rating result. In fact, the rule may be a means of ferreting out discrepancies, particularly in temperature records. If the temperature of a place is for any reason too high, the humidity records must be relatively too low, because the actual amount of moisture has not changed. I can not but believe that some of the large cities, like Chicago, New Orleans, Baltimore, and Boston (the 51st, 52d, 43d, and 49th, respectively, in the scale for winter), have been unjustly moved back toward dryness by the too high temperatures recorded there, where thousands of tons of coal are consumed each winter. T. C. Mendenhall, of the Ohio State Meteorological Bureau, in "Science" of March 14, 1884, in an article on "A Question of Exposure," called attention to the discrepancies between the State temperature observations and those of the Signal Service, pointing out the influence of exposure, of stone buildings—to which the Signal Service thermometers are attached—and of location, as giving higher records generally, and much less sensitive accounts of cold waves than the State observations, which are not usually located in the center of cities. He concludes: "There seems to be little doubt that for temperature measurements it would be well to put stations near rather than in large cities, and at sufficient distance from them to be free from purely local conditions."

TABLE III.

SIGNAL-SERVICE STATIONS IN UNITED STATES, RATED IN ORDER OF DRYNESS, ACCORDING TO THE CLIMATIC RULE FOR WINTER OF 1883, JANUARY, FEBRUARY, AND DECEMBER, WITH MEAN TEMPERATURE ADDED.

We should then consider the *physical effects of dryness* thus produced, and, if time would allow, draw appropriate conclusions, verified by experience, as to the beneficial effects of dryness in disease. All this is too much for a paper of this character—i. e., to do it thoroughly—so I may be excused if I trust wholly to summarizing the points of evidence except where I have something new to offer.

(To be concluded.)

THE ETIOLOGY AND PREVENTION OF TUBERCULOSIS.

By A. BRADFORD FARNHAM, M. D.,
MILWAUKEE, WIS.

LEADING advocates of the anti-germ treatment of disease have denounced as absurd any preventive treatment of phthisis not based primarily on anti-bacterial therapeutics. By such treatment it has been maintained that tuberculosis

may be stamped out. Destroy every bacillus and spore of a bacillus, and the disease must end.

The object of this paper is to discuss munitive or protecting therapeutics primarily, and incidentally the causation of phthisis.

That the bacillus may be a cause of tuberculosis all agree. Watson Cheyne's verifications were hardly needed, so full and conclusive was Koch's original proof. Many are questioning whether the bacillus is the only causative bacterium. I know of no trustworthy experiments proving a causative agency for any other bacillus or bacterium. Tausaint's cocci failed to produce the disease in Cheyne's hands. Experiments with other and indifferent irritants fail when the animals are removed from the germs of the laboratory. In short, it rests with future research to distinguish etiologically any other tuberculosis from the present bacillo-tuberculosis.

Every judicious disciple of Koch admits that the bacterium requires a special soil in which to develop, but at present the peculiarities of that soil are unknown. The question can never be settled by the mycologist alone. The pathologist and anatomist have their share to do. It is to pathologico-anatomical work that we must look for a final solution of many difficulties, if not for a final elucidation of the subject. As yet there is no accepted explanation of tuberculous predisposition. Beneke, Schottelius, and Formad have offered different solutions.

It may be eventually accepted that there are no mycological or anatomical peculiarities about the tuberculous diathesis, a depressed vitality due to any cause and exposure to the bacillus being the only factors needed for the development of phthisis.

Let me here comment on what seems a misapprehension on the part of the opponents of the bacillus. Formad, Leanning, and others assert a causative agency in the production of tuberculosis for many diseases and strong mental or physical impressions, in the wake of which the disease so often follows. Logically, it is wrong to make this assertion, however well it is to assume its truth in practical preventive therapeutics. To rule out all causation on the part of the bacillus, it must be assured that the animal tissues, weakened by the above-mentioned causes, have not been exposed to the irritating germ. It is difficult to have this assurance, as will be shown. In time some practical advance can be made by comparing the percentage in which disease is followed by tuberculosis in patients known to be exposed to the bacillus, on the one hand, and those apparently not so exposed, on the other.

Let me mention here what I have never been able to understand. How can the bacillus gain access to the circulation, presumably through the lungs, go on to the liver, kidneys, meninges, glands, testicles, joints, pleural cavities, or elsewhere, and develop only in some chosen tissue, passing by in disregard all others? Why does not the bacterium, once in the blood, develop in that presumably favorable medium in such numbers as to invade and occupy the whole organism? The common explanation of general tuberculosis is that the germ has entered the circulation. In this connection I see that Virchow, von Recklinghausen, and Rindfleisch are quoted by Formad as holding the opinion that certain local tubercular diseases are solely inflammatory in their origin. The dictum, too, that all cheesy degeneration is tubercular degeneration is certainly false. To give only one proof, Cheyne mentions, besides inflammation, the psorospermie as causative agents in this degeneration, without any aid from the bacillus.

The disease is not strictly contagious, like the exanthems, but requires a special soil—a previous weakening of the constitution. Leanning, as readers of the "Journal" know, thinks that spores are, perhaps, laid in tubercular cavities, where they develop and fly away to plant spores in similar soil. He maintains that most cases of the disease commence as fibroid, with plastic exudation, in which the bacillus is not a factor. This latter may be true, but more investigations must be made into the condition of lung tissues in this very initial stage of phthisis, much section cutting and staining

be done, before any such claim can be more than an assertion. A method of some value might be a daily searching examination of the sputa of persons affected with initial phthisis. If many examinations, competently made, show that the advent of the bacillus is coincident with ascertained softening, a point may be made against the primary agency of the bacillus. Those who would deny the claims of Koch and his followers must support their denials by work as good and conclusive as Koch's original proof. Lungs assuredly in this first fibroid condition will be obtained with difficulty if we rule out, as we ought, the lungs of animals inoculated with the bacillus.

Most men need not fear the disease. Williams says the direct conveyance of tuberculosis from one man to another by contagion is rare. Proof of this is abundant in the rarity with which nurses contract the disease. A wife contracts the disease from her consumptive husband because she has made herself susceptible by her unselfish and unthinking disregard of the laws of health.
